3. On the other hand, the empirical research mentioned above indicates a significant higher risk of future sexual assaults in people with pedophilic appetence than with other sexual, e.g., homo- or heterosexual, orientations. Furthermore, by far not all who sexually attack children are genuine pedophiles; some simply take advantage of the defenselessness of children, without a specific or exclusive sexual drive toward their young victims. Hence, being able to demonstrate with a high degree of reliability that someone who committed a sexual assault on a child really is pedophilic, as fMRI scans are apparently capable of, actually provides an important element for a sufficient cognitive basis to assess their risk of recidivism. And again, the same also holds for the prediction of future dangerousness of psychopathic violent offenders.

This warrants the following prospect: fMRI (and other) brain scans are or, at any rate, will certainly be well suited to contribute valuable assistance to the difficult task of prognosticating criminal recidivism in certain types of sexual or violent offenders. Thus, they might help us clear up some of the dark spots in the practice of preventive detention. We must, however, be careful not to allow them to rather add one further spot to that record: an excessive trust and hence a kind of mechanistic application of their results, based on an overassessment of their capabilities and an underestimation of their limits. There is no such thing as a "criminal brain." There are, however, mental dispositions to act in certain ways that raise the risk of becoming criminal in their possessors. Like all dispositions to act, they have their proximate (though of course not their only) causal source in people's brains. To identify them there and to draw legally relevant conclusions with the necessary skeptical diligence – that is the future task of courts, psychiatrists, and legal scholars. Probably rather sooner than later, the rapidly developing methods of neuroimaging will provide indispensable support.

Responsibility Enhancement and the Law of Negligence

85

Imogen Goold and Hannah Maslen

Contents

Abstract

Much of the law is concerned with ascribing responsibility. The law of negligence looks for the person who acted without due care and places on them the responsibility for the outcome. The criminal law responds punitively to those who break its rules, but the accused can avoid being held wholly or partially responsible if she can point to evidence that showed she lacked the capacity to be in charge of her actions. Contract law is based around competent individuals voluntarily taking on

obligations to one another and holds them responsible if they fail in them. Responsibility is demonstrably a key concept in the law of England, and therefore we should be particularly interested in technology that can affect an individual's capacity to be responsible. This chapter looks at one particular area of English law in which new drugs are potentially changing our capacities and hence (arguably) our responsibilities: cognitive enhancers. Using a scenario involving a tired surgeon, this chapter briefly examines the question: When, if at all, might someone be legally obliged to take a cognitive-enhancing drug?

Introduction

As the use of cognitive enhancers increases, so does the potential for legal claims. As the technology currently stands, the most likely claims will be for harm resulting due to negligence, and most often in the context of driving and provision of professional services, particularly clinical practice. This is in part because, at present, the most widely used cognitive-enhancing pharmaceuticals can be used to combat decreases in wakefulness and cognitive capacity that arise due to fatigue (Baranski et al. 2002; Caldwell 2005; Grady et al. 2010; Hart et al. 2006; Sugden et al. 2012). Consequently, in situations where the injury complained of happened due to the defendant's fatigue, it might be open to claim that the defendant could have avoided this if she had taken a cognitive enhancer. From a legal perspective, this raises three questions: Is there a duty to take such an enhancer (liability for omissions)? Does failing to take an enhancer breach the standard of care owed to the claimant? Can it be said that the failure to take the enhancer *caused* the injury? Each of these questions is briefly examined using a scenario involving a tired surgeon. The discussion focuses on the use of modafinil, as there is growing evidence of its efficacy in addressing fatigue. These questions, and most of the conclusions drawn in response to them, could be extrapolated to other contexts.

An alternative liability situation arises if the defendant *has* taken the enhancer and the claimant alleges that doing was negligent and caused the injury he suffered. Here, the questions would be: Does taking the enhancer breach the standard of care owed to the claimant? Can it be said that taking the enhancer *caused* the injury? These questions are legally simpler than those relating to a failure to take the enhancer, and their answers will be essentially determined by the possibility of linking taking the enhancer with causing harm, which is a matter of evidence more than law. For these reasons, these questions are considered only briefly at the end of this chapter.

There is also evidence that cognitive enhancers can lift cognitive capacity above the norm – either one's own norm or the general norm. For example, it appears that for some people, modafinil has the effect of increasing the length of time for which they can remain focused on a task, and for some it has the effect of increasing concentration and suppressing the need for sleep. In a situation where a person's normal capacity to focus would naturally wane and potentially lead to injurious

errors, taking a cognitive enhancer might prevent such errors. By increasing the person's capacity to concentrate beyond the norm, it might then be argued that their level of responsibility should rise accordingly. Such an approach has been explored in the philosophical literature and is briefly touched on below, but for the most part, the English legal system treats responsibility in negligence as a threshold concept. Given this, it is highly unlikely that English law will incorporate a system of enhanced responsibility in the near future, and so this issue is not dwelt upon here. However, it is noted that as our ability to cognitively enhance improves, this is likely to become an important area of legal research.

The chapter concludes by drawing together the threads of each of these three sections to argue that while there is support in the ethics literature for obliging the use of enhancers, and suggestion that responsibility should track capacity, it is not likely that these calls will be heeded by the English courts or legislature in the near future. On this point, the chapter briefly examines the relationship between legal and ethical obligations, as well as the impact of public demand, to demonstrate why these three sources of direction about how we should act do not always map onto one another.

Calls for Legal Requirements to Take Enhancers

The suggestion that individuals in certain jobs should take cognitive enhancers has emerged from a variety of places. Philosophers, lawyers, stakeholders, and even the professionals around whom the debate centers have considered whether a duty to enhance will be likely and/or justified. Some writers focus on the idea that it would be a good idea practically – it would be prudent to use enhancers to make things safer if possible. Others have suggested that there could be a moral obligation for professionals in high-risk jobs to enhance. Still others have described how changing attitudes and practices might indirectly generate a legal duty for these professionals to enhance. The recent report from the Joint Academies' workshop on "Human Enhancement and the Future of Work" (2012) suggests that people may see a moral obligation for some individuals to use enhancers at work or even demand that they do so:

> [O]ccupations that require particular patterns of focus could benefit from enhancements that facilitate achieving such patterns. For example, surgeons may need to be able to concentrate for extended periods, whereas other jobs such as air traffic control can require very rapid reactions during periods of relative uniformity. As an extrapolation to this, it is possible that in these high-responsibility occupations enhancement could be seen as a moral obligation, or even demanded by the public.

While a perceived moral obligation would make the conduct of the high-responsibility professionals open to moral evaluation, public demands for enhancement could put pressure on those guiding professional practice to impose a duty to enhance. Ethicists have suggested that there are other domains in which enhancement should be routinely adopted. Discussing cognitive enhancement in courts, Sandberg et al. (2011) claim:

> As our range and knowledge of cognitive enhancers increases, some enhancers should be provided, as we now provide coffee, if they are safe and do not bias judgement. Substances like modafinil may well meet this criterion. Given the stakes, we have a moral imperative to investigate ways to utilize these new technologies to improve cognitive performance in the courtroom. Innocent people's lives may well depend on them.

The suggestion that there may be a moral obligation to enhance is not confined to academics. Some of the professionals who might be expected to take enhancers also share the view. The editors of the Mayo Journal of Clinical Proceeding, both medical doctors, have asked:

> What if a legal stimulant that is shown to be safe could be used to improve medical care during periods of fatigue, regardless of the number of hours worked? Would not the more ethical choice be to promote the reduction of errors — First, do no harm? With publication of original research [. . .] use of prescribed drugs to promote wakefulness in the absence of comorbidities, such as narcolepsy and sleep apnoea, will undoubtedly move from the military into the public arena. (Rose and Curry 2010)

The editors think that the use of drugs to promote wakefulness is likely to move into the public arena and that this would be the ethically correct course of action in medicine, according to the professional standards guiding practitioners' conduct.

Writing in the Journal of Surgical Research, surgeons have also suggested that it may come to be required practice. They say:

> The prospect of fatigued surgeons taking a prescription drug, such as modafinil, to allow them to operate for longer, and possibly to a higher standard, is perhaps not as far-fetched as some may suggest. This drug has already been trialed in emergency physicians, when performing non-medical-related tasks at the end of a nightshift. (Warren et al. 2009)

They also emphasize that the concept of surgeons risking their health to benefit patients is not an alien one. They cite operating on patients with blood-borne transmissible diseases as an example of where the risk to the surgeon is felt justifiable to improve the patients' chances of recovery. Having noted that there are "useful and warranted forms of coercion" such as forcing surgeons to undertake hygiene practices such as handwashing prior to and during surgery, they ask:

> What will our employers feel about a drug that makes us less prone to error, able to work longer hours, or to operate more efficiently? Employers are able to request certain behavioural standards from their employees, dictate rest periods, and insist on abstinence from certain drugs to ensure that their doctors perform well — will a day arise where they can recommend or even insist on surgeons being artificially enhanced? This may seem fanciful, but recent work has suggested that a mixture of napping and caffeine attenuates fatigue in interns and thus should be adopted by hospital administration. Why not other types of stimulant?

As evidence of the plausibility of this prediction, regulators in Australia are already considering the practical dimensions of using stimulants like modafinil as a fatigue-management strategy. Queensland Health, the medical regulatory body of the North-East Australian state, in their Fatigue Risk Management System Resource Pack (2009) note:

> To meet the needs of patients at any time of the day or night, . . . doctors and other healthcare workers . . . often work long hours — throughout the night and on-call over weekends, public holidays and other times of need. This presents us with the challenge of fatigue and its associated risks to staff and patients. To meet this challenge, fatigue risk management must be included in our core business operations.

The report suggests that doctors could take "[n]aps of less than 30 min in length [t]o provide measurable boosts in alertness and performance" and up to "400 mg of caffeine [which is the] equivalent to about five to six cups of coffee" because "[c]ompared with other psychoactive drugs (e.g., modafinil), caffeine is . . . more readily available and less expensive." It should be noted that this discussion only cites the availability and expense of modafinil as counting against its use as a way to manage fatigue. Both of these barriers could be removed in the future, leaving the possibility of future reports recommending the use of psychoactive drugs like modafinil.

Further, there are domains where enhancement could already be required. Noting that the US Uniform Code of Military Justice requires soldiers to accept medical interventions that make them fit for duty, Ravelingien and Sandberg (2008) have suggested that this is at least one domain where wake enhancement may be explicitly required. They further suggest that "[i]t is conceivable that the availability of safe and effective wake enhancers will create or fortify a responsibility to ensure that fatigue no longer affects performance, particularly within professional contexts."

Whether such a responsibility will be legally enforceable is a question that has also received a tentative "yes" from legal scholarship. Chandler (2013) has argued that civil law might indirectly require surgeons to enhance, as what is viewed as delivering "reasonable care" changes. She suggests that such changes could have the effect that a failure to adopt novel neurotherapies that remedy cognitive limitations would be negligent if it could be shown to have led to harm. She emphasizes the indirect way in which this could occur:

> Cognitive deficits may also raise the risk of liability if they cause a physician to make errors that would not be made by the reasonably prudent practitioner in the field, or to fail to keep up with developments in the field to an extent that is considered to fall below the reasonable standard of care in the profession. In such cases, the courts would simply find there had been a failure to maintain the standard, without necessarily commenting on cognitive deficits or therapeutic methods to alleviate them.

A Legal Obligation to Enhance?

Could someone be legally obliged to enhance themselves? This question prompts consideration of the most likely scenario in which this might occur – a scenario in which a person has fallen below normal capacity and taking an enhancer would bring them back to normal capacity. In the scenario, the person does not take the enhancer and someone is harmed. The injured party brings a claim in negligence. This then raises three questions: Did the person have a duty to take the enhancer

(the duty question)? Is the failure to take it a breach of that duty (the breach question)? Could the failure be said to have caused the injury (the causation question)? These questions are likely to be the same questions asked in other jurisdictions, but the answers may differ. The analysis that follows presents answers based on English law.

The first question potentially involves what is called liability for a pure omission. The English common law makes a fundamental distinction between acts and omissions. Generally, if I foresee, or can reasonably foresee, that my action might harm another, I am under a duty not to act. However, the same is not true of omissions. Merely foreseeing that a *failure to act* might lead to harm does not, without more, legally *oblige* me to act. As Lord Diplock stated in *Dorset Yacht Co Ltd v Home Office* (1970):

> The very parable of the good Samaritan (Luke 10, v. 30) which was evoked by Lord Atkin in *Donoghue v Stevenson*. . . illustrates, in the conduct of the priest and of the Levite who passed by on the other side, an omission which was likely to have as its reasonable and probable consequence damage to the health of the victim of the thieves, but for which the priest and Levite would have incurred no civil liability in English law. (*Home Office v Dorset Yacht Co* 1970)

Even doctors, nurses, and other medical practitioners who come across someone in need of medical attention for whom they have not previously assumed responsibility will not be liable for failing to act (Deakin et al. 2008; *Stovin v Wise* 1996; *X v Bedforshire CC* 1995).

This reluctance stems from a commitment to protecting and promoting individual liberty, as well as equity concerns (the "why me?" objection to imposing liability on one person who does not act, while leaving another bystander not open to liability). Liability for pure omissions will be imposed in certain situations, such as where a person has created a source of danger or failed to warn about a danger where she ought to do so (see *Kane v New Forest DC* 2002) and also those in which a person is in relationship of control with a third party, where the latter causes the harm (*Home Office v Dorset Yacht Co* 1970). In addition, a person can become obliged to act if he voluntarily assumes responsibility for someone else, whether by agreeing or indicating that he will do so (*Hedley Byrne v Heller* 1964; *Barrett v MOD* 1995). It is on this basis that surgeons come under a duty to undertake positive acts in the care of their patients and so can be held liable for negligent omissions. This assumption occurs at the moment they agree to treat the patient, and from this point onwards, the surgeon must act in accordance with the accepted practices of a responsible body of medical practitioners (*Bolam v Friern Hospital* 1957). The special relationship that arises places on surgeons the duty to *do* (and refrain from doing) particular things to protect their patients' interests (Jackson 2010). This encompasses a duty not to exacerbate the situation, but the defendant will generally not be liable if the claimant is left no worse off than he would otherwise have been (*East Suffolk Rivers Catchment Board v Kent* 1941). Therefore, in such situations, it is well established that the practitioner may be liable for failing to act, and so this is one context in which liability for failure to enhance is most likely to be found, if it can be found at all. The following scenario is drawn upon to explore liability in this context.

The Scenario

A fatigued surgeon has worked 36 h without rest and is on her way home when an emergency case arrives. She is the only available surgeon qualified to perform the surgery. Despite knowing she is exhausted, she believes she can remain sufficiently capable for the duration of the surgery the patient needs. She expects the procedure to take around 2 h but recognizes that there is a risk that she might make an error due to her fatigued state. She also knows that the only other option is for the patient to be sent to the nearest hospital, which is more than an hour away. She knows that within the hour the patient's condition will deteriorate considerably and that there is the possibility that he will suffer harm as a result. She is faced with an unenviable choice but decides to perform the surgery.

As she is about to begin, she remembers that she has recently been taking a new kind of medication: modafinil. She has found that it makes her more alert when tired and enables her to concentrate better on complex tasks. Now a third choice presents itself. She could ask a nurse to get the medication for her and take it to counteract her fatigue.

The Duty Question

In our scenario, it is well established that the surgeon has a duty of care; for, as noted earlier, medical practitioners will be held liable for negligent omissions made in the course of patient care. The key question is whether a failure to take an enhancer will breach that duty.

While it is unlikely that the surgeon's employing hospital has a duty to ensure that a patient receives careful treatment,[1] it will have a primary duty to provide competent staff and proper facilities. This duty probably extends to providing properly skilled medical staff and an adequately equipped hospital, and this might include avoiding situations in which there are insufficient staff, leading to a surgeon making a fatigue-related error.[2] The hospital will also be vicariously liable for tortious omissions made by the surgeon during the course of employment. Therefore, if the surgeon is liable for failing to enhance, then the hospital that employs her will be vicariously liable on her behalf.

The Breach Question

The breach question (or put another way, the standard of care required of the surgeon) is approached in a specific manner in the context of medical treatment.

[1]See *A (A Child) v Ministry of Defence* (2004) EWCA Civ 641.

[2]See *Bull v Devon AHA* (1993) 4 Med LR 117; *Wilsher v Essex Area Health Authority*; *Re R (a minor) (No. 2)* (1997) 33 BMLR 178.

It still takes the essential risk-benefit approach, but in a way tailored to medical practice. If we ask "what must a surgeon do to fulfill her duty of care towards a patient for whom she has assumed responsibility?," the answer is provided by what has become known as the "*Bolam* test," after *Bolam v Friern Hospital* (1957). According to the test, a defendant "is not guilty of negligence if he has acted in accordance with a practice accepted as proper by a responsible body of medical [persons] skilled in that particular art." In our scenario, the question for the court would be whether a responsible medical practitioner would use enhancers in this situation. The answer at the present moment would obviously be that it is not: the use of cognitive enhancers is not mainstream practice, and a body of medical persons who would testify to this could easily be found. Therefore, this omission is unlikely to be a breach.

Since 1998, the assessment of the standard of care is no longer determined solely by a body of medical practitioners, and the court must now be ". . .satisfied that, in forming their views, the experts have directed their minds to the questions of *comparative risks and benefits* and have reached a *defensible conclusion* on the matter" (*Bolitho v City and Hackney HA* 1998). This is known as the "*Bolitho* gloss" on the test. Following *Bolitho*, the defendant's actions will not be excused merely on the basis of the support of her peers if they lacked a logical or reasonable basis. Therefore, even if the defendant could point to a body of medics who asserted that they would not use cognitive enhancers, if it became apparent that cognitive enhancers cheaply and effectively reduced risk, a judge would be able to (but would not necessarily have to) find the expert's testimony indefensible. The consequence of this is that if taking an enhancer was clearly safe and efficacious, posing little or no risk to the surgeon and having demonstrable benefits for the patient, then it is very likely that a failure to enhance would breach her duty and conversely that taking it would be the responsible course of action. Taking the modafinil would be equivalent to many other simple, non-harming precautions that a responsible surgeon would, following *Bolam* and *Bolitho*, be expected to take. Handwashing is one simple example. Wearing glasses would be another (*Stefanyshyn v Rubin* 1996).

However, at present, this could not be said for cognitive enhancers. For example, it is not yet established that modafinil is safe (Kumar 2008; McBeth et al. 2009). Most studies analyzing the effects of modafinil were small and generally did not use a standardized method for assessing adverse reactions, but there are reports of a range of side effects associated with modafinil. These include headaches, dizziness, abdominal pain, dry mouth, nervousness, restlessness, sleep disturbance, and heart palpitations. It is important to note also that the majority of studies conducted on modafinil were short-term or single-dose studies and hence do not provide much data about long-term implications and the potential for dependency (Kim 2012; Repantis et al. 2010; cf. Randall et al. 2004; Sugden et al. 2012).

Given these potential risks, and English law's resistance to requiring people to risk their own safety for others, it is unlikely there would be any expectation on a medical practitioner to take an unproven pharmaceutical. This is particularly likely given the English legal system's difficult experiences dealing with the legacy of asbestos, thalidomide, diethylstilbestrol (DES), and nicotine, which were all

considered safe until their deleterious health effects emerged, often with tragic consequences (*Fairchild v Glenhaven* 2002; Dunea and Last 2001).[3] Therefore, enhancement would be considered merely going above and beyond the call of duty, but not expected, and failing to do so would not be a breach.

These concerns are further strengthened by other, less obvious, implications of taking modafinil and other enhancers. While the drug does restore wakefulness, it does not remove the need to sleep. Users must still make up the sleep later; otherwise a "sleep-debt" is built up, which has well-established negative impacts on health. At present, the move is towards reducing doctors' hours. It is unlikely that this alternative means of robbing them of their sleep will find support, as it would go against current policy trends and also promote the normalization of a drug that leads eventually to chronic fatigue.

Additionally, once taken, one cannot simply "switch off" the effects of an enhancer. For example, modafinil loses its pharmacologic activity over time, decreasing by half around every 12–15 h (Robertson and Hellriegel 2003). Put another way, it takes a while to wear off. Consequently, a surgeon taking the enhancer will potentially remain awake for many hours beyond the time when she has completed the surgery. It will be difficult for her to fall asleep, and she will push back the time at which she goes to bed. If she has to work at her normal time the next day, she will have less sleep and be less refreshed (Gill et al. 2006). Unless she is fortunate enough to have an opportunity to catch up her lost sleep, she will very likely have to come to work at her normal time on her next working day and so will both accrue a sleep-debt and be fatigued at work.

Another concern that speaks against failure to take an enhancer being a breach is the lack of demonstrated consistent efficacy. It cannot be said that a surgeon *ought* to take the modafinil if we cannot say with sufficient certainty that doing so would be effective, as we would then be finding the surgeon in breach of duty for something that may have been irrelevant in the circumstances. The efficacy of most enhancers is yet to be conclusively proven (Lynch et al. 2011; Turner et al. 2003). Even modafinil, which appears to be the most effective, produces varied responses in different studies. Some studies do show improvements on some aspects of performance that are otherwise affected by fatigue – for example, modafinil has been shown to improve some aspects of decision making. However, there is little proof that modafinil improves the deficits in psychomotor performance that result from fatigue (Sugden et al. 2012). Similarly, while some studies showed improvements in attention, others failed to do so (Randall et al. 2004).

The effects of enhancers also vary between people in the extent to which they improve various cognitive capacities. For some, modafinil addresses fatigue effectively or leads to clear improvements in cognitive capacity. However, in others it has little or no effect (Finke et al. 2010). It is also known that the impact of modafinil on an individual varies with the context in which he takes it (Thomas and Kwong 2006). The idea of a duty to enhance rests on the notion that in doing so,

[3]We are indebted to Professors Peter Cane and Jane Stapleton for inspiring our ideas on this point.

the chances of harm are reduced. But this cannot be the case if the efficacy of the enhancer is so variable that its effects are not highly predictable.

For all of the reasons given in this section, and the general resistance to a duty of rescue, English courts are unlikely to extend a surgeon's duty to risk her own health for the sake of a patient by taking a relatively untested pharmaceutical. However, those who do take it are probably not in breach unless a clear causal link between taking the modafinil and the resulting harm can be established. The issues discussed in the next section demonstrate how difficult this would be.

The Causation Question

If the seemingly insurmountable hurdle of the second question could be overcome, the third question – causation – provides yet another barrier to finding that someone should take an enhancer or face legal liability. Under English law, a defendant cannot be liable in negligence unless it can be said that the negligent act or omission *caused* the loss that is the basis of the claim. The court must ask whether the loss would have occurred "but for," or without, the act or omission that constituted the breach (*Barnett v Chelsea & Kensington Hospital* 1968).

Applying this to the fatigued surgeon who omits to take modafinil, the question for the court would be whether "but for" the surgeon's failure to take the enhancer, the patient would have suffered the injury. In the scenario, the breach of duty was the surgeon's failure to take a cognitive enhancer. However, given that it is being assumed (plausibly) that cognitive enhancers are effective at remedying fatigue, the causal uncertainty before the court lies in the effects of persistent fatigue on surgical performance. The cause of the harm in the scenario is the fatigue, the breach is the failure to correct it, so the court would have to find that the fatigue that the surgeon failed to remedy was causally linked to the harm that eventuated.

There are two principal sources of uncertainty that might prevent the court from proving the causal link. The causal link must be shown on the balance of probabilities; that is, it must be more likely than not. The first source of uncertainty is that the effects of fatigue on performance are not clear-cut and the second is that some risks inherent in surgery can materialize blamelessly. Each of these is explained in turn.

The effect of a surgeon's fatigue (and, hence, her failure to remedy it) on surgical performance will depend on the particular procedure in question and, probably, the particular surgeon. Was it a procedure that needed expert manual dexterity? Was it a procedure that required paying attention to many things at once? Was it a procedure that required a high level of teamwork? Fatigue will affect a surgeon's ability to meet the cognitive demands of surgery to a greater and lesser extent, depending on those required for the particular procedure. Further, enhancement drugs (while having the general effect of increasing subjective wakefulness) may improve performance in some ways but have no effect on, or even impair, other domains of cognition (Repantis et al. 2010). Further still, while surgeons will have developed their own strategies for managing their fatigue, the court could not be

sure that taking an enhancer will not cause some to overestimate their capacities, perhaps *increasing* the likelihood of error (Buguet 2003). This means that the link between the uncorrected fatigue and the harm will always be speculative. Whereas, for example, not giving a patient enough oxygen or administering an overdose of a drug has known and measurable effects, the effects of operating while fatigued are indeterminate. Whereas a court can relatively confidently know what would have happened had the patient not been given an overdose, it will be very uncertain what would have happened had the surgeon taken an enhancer, i.e., whether the harm would have occurred *but for* the breach.

The second source of causal uncertainty stems from the fact there are always risks involved in surgery, which are often blameless if they materialize. These sorts of risks are explained to patients when they consent to an operation or other procedure. It would be very difficult to know whether or not some instances of harm were risks that materialized blamelessly or were consequences of the fatigue. Much will depend on the precise details of the case: the particular procedure that took place, the level of cognitive and manual dexterity involved, the risks inherent in the procedure, the probability that these risks materialize, and so on. Any risk created by the surgeon's fatigue does not remove or subsume the risks that were already present. The surgeon will not be liable for these risks if she has adequately explained them to the patient prior to obtaining consent to the surgery (but will remain potentially liable for any risks that arise due to her failure to take due care). Consequently, there are some risks that can occur blamelessly (i.e., not due to negligence, but simply as part of the normal procedure) and for these the surgeon will not be blamed (if fully informed consent has been obtained). Given this, it would be unfair to assume a link to fatigue where the surgeon omits to enhance. If some harms can occur blamelessly when the surgeon is alert, why not also when fatigued?

So, establishing causation would require the court to clearly conceive the causal mechanism from breach to injury, understanding the role which uncorrected fatigue might play in it. Interpersonal differences in the experience of fatigue and the uncertainty about its precise effects on surgical performance make this a huge empirical challenge. The assessment is further confounded by the fact that the risks inherent in surgery often materialize blamelessly. Even on the balance of probabilities standard, courts would likely be unable to establish causation.

When Enhancers Cause Harm

Our focus has been on the failure to enhance up to normal capacity, but it is possible that a claim might be brought for harm caused by the decision to enhance. This would operate in the same way whether it was to bring the person up to their normal level of capacity or beyond it. The first question is whether the defendant was under a duty to take care in the situation. To answer this generally, or in the abstract, is difficult. Duties of care relate to the context in which the act is done, and there is often existing case law that determines whether an act can be considered negligent

in context. Therefore, the question cannot be answered in the abstract in any meaningful way.

The vital question, however, will be the second question: could taking an enhancer be said to breach the duty? Put another way, would taking an enhancer fall below the expected standard of care? Would it be something a responsible surgeon would not do? Necessarily, this standard is related to the duty imposed in the context, but some general comments can be made about how the question might be approached. Breach is determined by assessing the balance of risks in a given situation. In considering how to act, one must weigh the magnitude of the foreseeable risk that the harm will eventuate if one acts. Where the risk of harm is high, and the cost of avoiding this risk is low, carrying out the risky action will be a breach of duty. Conversely, where there is a very low risk of harm, and the cost of not acting is high, then it may be reasonable to act and there will be no breach (*Miller v Jackson* 1977; *Bolton v Stone* 1951).

How would this calculus be applied where a person takes a cognitive enhancer? It would depend on the context, and it is difficult to analyze in a vacuum, so the focus will be on the surgeon again. Supposing she chooses to take a cognitive enhancer while at work because it helps her to concentrate, and it will be presumed that the enhancer will definitely have this effect. For this action to be injurious to another (and hence open the door to her being liable in negligence), taking the enhancer must allegedly be harmful to someone else. This will be very difficult, as taking the enhancer only directly affects herself. Perhaps it could be imagined that in becoming so focused, she tends to focus on one task to the exclusion of others. This leads to her to ignore some aspects of patient care, and the patient is harmed as a result. Alternatively, she takes the enhancer to ensure she can stay awake during a very long surgery, but this means she becomes too focused on one aspect of the surgery and neglects another, leading to a harm. In either case, the law would weigh the risks to the patient (neglecting patient care) against the costs of not taking it (i.e., the benefits of taking it such as improved concentration). The best that might be said in such an abstract situation is that the risk of harm, if very serious, would quite likely outweigh the benefits given that most doctors manage to care successfully for patients without enhancing themselves.

The third question, the causation question, also poses significant difficulties. As explained earlier, to prove causation, it must be shown that but for the breach of duty, the harm would not have occurred on the balance of probabilities. Where the breach is the taking of an enhancer, a causal link between taking that enhancer and the resulting harm needs to be shown. We must be able to say that but for someone taking the enhancer, the harm to the claimant would not have occurred. The enhancer would therefore need to have some harming effect in this context. If modafinil is taken as the example, as seen above, it could be speculated that it made the surgeon too focused, but a surgeon is already concentrating very hard in the context of surgery. It is self-evidently almost impossible to show that it was, more likely than not, only the *that extra* concentration attributable to the modafinil (as this is the breaching act) that led her to ignore an aspect of patient care, which in turn led to the harm complained of.

The other possible harming effect of taking modafinil that might be imagined is the accrual of a sleep-debt noted above. It could be argued that taking the modafinil earlier caused the surgeon to experience the effects of the sleep-debt during this patient's surgery and thus become fatigued and make an error related to that fatigue. This is again highly likely to fail, partly because it falls foul of the problems noted in the previous section on linking fatigue to harm but compounded by the many intervening factors between the original taking of the modafinil and the later sleep-debt and consequent error. Many breaks in this causal chain could be suggested, and establishing causation would be difficult, if not impossible. Even if factual causation could be established, the remoteness limitation that restricts liability to reasonably foreseeable consequences would also very likely prevent liability being found in such a situation (*Overseas Tankship v Morts Dock Ltd* 1961).

Does Enhanced Capacity Give Rise to Enhanced Legal Responsibility?

A related question is whether surgeons who were cognitively enhanced should be held more responsible – held to higher standards. The assumption underlying this idea is that as a person's mental capacities increase, so does their level of responsibility. Nicole Vincent has articulated this "capacitarian" thesis and illustrates it as follows:

> [I]n lay contexts responsibility is often thought to require such things as the ability to perceive the world without delusion, to think clearly and rationally, to guide our actions by the light of our judgments, and to resist acting on mere impulse. This is, for instance, why children, the senile, and the mentally ill are thought to be less than fully responsible for what they do (i.e. because they lack the right kind and/or degree of mental capacity), why children can acquire more and/or greater responsibilities as they grow up (i.e. because their mental capacities develop as they mature), and how responsibility is reinstated on recovery from mental illness (i.e. because the needed mental capacities are recovered). (Vincent 2011)

Elsewhere (Vincent 2013), she suggests that the implication of the capacitarian thesis is that as capacities are enhanced beyond the "normal" range, the people in possession of these capacities might in some sense become "hyper-responsible." This means that these people should be held *more* responsible – are more blameworthy – when things go wrong. If this theory is correct, then there are obvious implications for surgeons who use enhancers: once enhanced, a higher level of proficiency can be expected of them. Would enhanced surgeons become liable for errors that previously would have been tolerated as results of inescapable human error? While this remains an interesting question for moral philosophers, the law is unlikely to reflect the capacitarian implications. In negligence law, an individual's precise capacity is not generally relevant to the existence of a duty and its breach, as the standard is the objective standard of a reasonable person. The learner driver is held to the same standard as the professional racing driver. In the context of surgeons, the standard of care will be that of the reasonable surgeon. It is unlikely that a different standard – that of the reasonable enhanced surgeon – would be

expected from those surgeons that enhanced. However, were enhancement to become mainstream practice, and were there to be a consistently higher level of proficiency as a result, it is conceivable that what is expected of the reasonable surgeon might rise. This happens with the introduction of all different kinds of technology and practices to clinical care: the standards expected now are higher than those expected 50 years ago, but this happens across the board and is not idiosyncratic to individual surgeons' cognitive or other capacities.

At present, English negligence law remains tied to responsibility as a threshold concept, determined by either reasonableness or the responsible practitioner standard, and there is little to suggest that this will change in the near future. However, whether the capacitarian approach will find a foothold remains to be seen, and there is much further useful work to be undertaken on the questions raised in this section.

The Right Role of the Law: Legal Responsibility, Ethical Obligations, and the Demands of the Public

The arguments put in the ethical and philosophical literature in favor of professionals being obliged to enhance themselves may well be sound. It might well be the case that it would be the right thing to do, ethically speaking, for a tired surgeon to take modafinil to enable her to take on a surgery she might otherwise not be able to perform. A pilot might be morally obliged to enhance himself to reduce the risk of errors, given the potentially catastrophic consequences if he cannot safely pilot the plane. So too the public might legitimately wish these professionals to self-enhance to help prevent the possibility of harms. Very often, the law will follow or be strongly influenced by such ethical obligations and the views of the public. However, for two main reasons, this will not always be the case.

The first of these rests on the role of the law in society. The law is an organizing system, guiding our behavior to enable us to achieve our individual and collective goals. Although it depends on one's jurisprudential stance, it is probably uncontroversial to hold that the law should afford us the greatest amount of liberty that can be achieved while still protecting the liberty and interests of other members of society. One might go further and argue, as Joseph Raz does, that the law's role is not simply to facilitate liberty and pure choice but to promote autonomy in the rich sense of choices that contribute to human flourishing. On this view, the law ought to offer us a range of *good* choices, which should be more attractive than those that are less likely to promote our interests (Raz 1986). Whatever stance is taken, it is also uncontroversial that the law should be sufficiently clear and stable to effectively guide behavior – the rule of law demands that citizens are able to determine with reasonable certainty what they may and may not do.

To find liability in the context of enhancement, then, the law would need to be able to very clearly define when enhancement would be required. This requires a degree of certainty that the ethical obligations described earlier in this chapter lack. In situations where the risk to the surgeon from enhancement is low, and the risk to the patient otherwise very high, it will be clear that there is a moral

obligation to enhance and save the patient. However, there will be many situations in which this is not so. While it might be obvious that a passerby is morally obliged to turn over the drowning baby in the puddle because there is no risk to himself, the determination of risk is exponentially more difficult when the puddle becomes an ocean. It cannot be said with certainty that the risk in saving the baby in the ocean would be negligible and so would arrive at a situation where the law would be compelling one person to risk themselves for another. This would require not only a risk-benefit analysis as discussed above but would further demand that the law could determine the precise level of risk that a bystander ought to take on to help another person (in the absence of any assumed responsibility). Such precision would be crucial, because it would determine whether or not the bystander would be liable for the resulting harm (from not aiding the person in peril) and would also deem that bystander's moral failure *the legal cause* of the harm, despite his lack of involvement in the situation in any other causal sense. These points, coupled with the English legal system's commitment to promoting and protecting individual autonomy, leads it to eschew requiring people to act even though it would be moral to do so. This is strengthened by the fact that a failure to do as the law demands in such a case does not lead just to moral disapprobation but sanctions. These might be a requirement to compensate but in some contexts might involve punitive measures and the labeling of the person who did not risk themselves for another as a criminal.

This divergence between ethics and law arises further because the law must apply to everyone and it must be discoverable and sufficiently certain as to be an adequate guide to behavior. It cannot so easily take account of the nuances of a particular situation like that in the preceding paragraph, so it must draw a line and put forward a principle that can be definitely stated and stood by. For this reason, the law will not always map directly onto the terrain so carefully teased out by the ethics of a situation. In the context of medicine, the contrast in approaches is spelt out neatly by a comparison of the Hippocratic Oath – first, do no harm – and the law's position, do not make the situation worse. The question of what constitutes harm in any given situation will be complex, subtle, and potentially vexed. A directive not to make things worse (or otherwise face sanction) is more certain, perhaps more blunt, but probably a more workable guide to behavior that would otherwise attract legal response.

The law must also demand or prohibit behavior to ensure the protection of all citizens. If self-enhancement carries risks, then this must come into the equation not only in the individual case as above but also when considering the wider, systemic effects of expecting individuals to enhance themselves. As seen above, if the law finds that failing to enhance is a breach of duty, this necessarily creates a widespread obligation on many professionals to regularly self-enhance to avoid the possibility of being found legally liable for harms. This shifts the norms in their workplaces, and a shift to regular enhancement as the workplace norm would consequently place significant strain on individuals. This might also lead to defensive practices where, for example, doctors' choice of patient treatment is determined in part by a desire to avoid liability, rather than solely based on what is most likely to cure.

Conclusion

This chapter has briefly explored one context in which calls have been made for a particular group of professionals to begin using new enhancement technologies for the benefit of others. While there is much, morally, to recommend surgeons doing their best to save others where the cost to themselves is low, the law cannot easily take this position. For good reasons, the English common law resists imposing liability (and consequent sanctions and demands for compensation) on those who fail to act. For surgeons, they are to be judged by a standard determined by their peersand by the evidence in support of a practice. At present, such a standard would not, in our view, demand that a surgeon take an enhancing drug. The law also demands a high degree of probability that an action has caused the harm complained of. Such an approach is only fair when the defendant faces paying significant compensation if the causal connection is made. The law must be sure that responsibility has been placed on the right shoulders. Given the state of the science, and our capacity to determine why a harm has arisen, it is highly unlikely that such a causal connection could be established between either taking an enhancer when the surgeon should not or a failure to take when she should. It is, for the reasons given in this chapter, even more unlikely that a surgeon will be expected to enhance herself beyond the norm. Given this, it should be concluded that, at the current time, English law is unlikely to find a surgeon who takes, or fails to take, an enhancer liable in negligence.

Abstract

As our understanding of the brain increases, it seems likely that new biomedical techniques for altering human behavior will be developed. One potential application of such techniques is within the context of the rehabilitation of offenders. This prospect may seem attractive, given the social and economic costs of crime and the limited effectiveness of traditional punishments at reducing reoffending (see, e.g., Ministry of Justice. *Proven re-offending statistics, quarterly bulletin*. October 2010–September 2011. England and Wales. Available at: https://www.gov.uk/government/publications/proven-re-offending–2, 2013). On the other hand, the fact that the brain is so intimately connected with an individual's identity, personality, and capacity for making autonomous choices gives rise to distinct concerns about the use of directly interfering with brain functioning. This chapter begins by indicating a number of neuroenhancements that might be used in rehabilitation programs in the future, if sufficiently safe and effective. Secondly, it outlines and replies to some of the main arguments for prohibiting neuroenhancement of offenders altogether. Thirdly, it examines the opposite position – that neuroenhancement of offenders should be mandatory. Fourthly, it argues that the case for mandatory interventions is ultimately unpersuasive. Provided sufficiently safe and effective interventions are developed, the best policy would be to provide such interventions on a voluntary basis. The chapter ends by discussing some of the issues that need to be addressed to ensure that offenders' consent to neurointerventions is truly voluntary.

Introduction

Currently, pharmacological and surgical means of affecting brain function are primarily used to treat mental and neurological disorders. However, as neuroscience progresses, we may increasingly be able to use brain interventions to alter behaviors that are "medically unremarkable but socially undesirable" (Farah 2004). For instance, brain interventions may be employed as part of offender rehabilitation programs and potentially offered as a condition of early release from prison. This prospect may seem attractive, given the social and economic costs of crime and the limited effectiveness of traditional punishments at reducing reoffending (see, e.g., Ministry of Justice 2013). On the other hand, the fact that the brain is so intimately connected with an individual's identity, personality, and capacity for making autonomous choices gives rise to distinct concerns about directly interfering with brain functioning.

The aim of using brain interventions in rehabilitation programs is largely to benefit society, by improving the moral conduct of offenders, rather than to further the best *medical* interests of the recipient. (For that reason, this chapter will employ the terms "neuroenhancement" or "neurointervention" rather than "treatment.") This also raises important issues about the appropriate relationship between the state and the individual and the circumstances under which the individual's interests could be overridden by the needs of wider society.

This chapter will begin by indicating a number of neuroenhancements that might be used in rehabilitation programs in the future, if sufficiently safe and effective. Secondly, it will outline and reply to some of the main arguments for prohibiting neuroenhancement of offenders altogether. Thirdly, it will examine the opposite position – that neuroenhancement of offenders should be mandatory. Fourthly, it will argue that the case for mandatory interventions is ultimately unpersuasive. Provided sufficiently safe and effective interventions are developed, the best policy would be to provide such interventions on a voluntary basis. This chapter will end by discussing some of the issues that need to be addressed to ensure that offenders' consent to neurointerventions is truly voluntary.

Examples of Potential Neuroenhancements

Increasing Empathy

There is some evidence to suggest that the ability to empathize is key to understanding moral norms (Blair et al. 2005). For example, individuals with markedly reduced levels of empathy have exhibited difficulties in distinguishing conventional rules (such as rules of etiquette) from moral rules and in ranking wrongs in order of seriousness. Philosophers differ as to whether empathy is essential for moral understanding. However, even those who believe that it is not essential often maintain that it is indirectly helpful in moral development. If techniques were produced which increased empathy in individuals who appear to be deficient in it, then this might play a useful role in reforming offenders.

Decreasing Violent Urges

Certain offenders may experience repetitive violent fantasies and powerful surges of anger which they find difficult to control. These factors can impair offenders' ability to think clearly about how they should act and may distort their moral judgments. Research is beginning to uncover certain neurological factors that seem to have an impact on individuals' dispositions to anger and violence. There is some evidence that selective serotonin reuptake inhibitors (SSRIs) may reduce aggression (Ferari et al. 2005; Douglas 2008; Crockett et al. 2010). It may become possible in the medium-term future to develop techniques which can reduce the strength of offenders' volatile impulses or which increase their control over these impulses.

Anti-libidinal Medication

Drugs have already been developed to help reduce deviant sexual urges and thoughts. This can create an opportunity for offenders to concentrate on the reasons why they should change their behavior and the steps they need to take, without being distracted by their impulses. These medications are already being used to some extent within the criminal justice system (Harrison and Rainey 2013).

Decreasing Racist Sentiments

Certain individuals experience a strong negative emotional reaction to members of different races. Such emotional reactions may stem from early childhood experiences, e.g., parents who taught them to fear members of a different race. Such deeply rooted emotional reactions may help to fuel racially motivated crimes and may interfere with the racist's ability to see why racism is wrong. Some research has been undertaken into the neural basis for racial stereotyping (Hart et al. 2000; Phelps et al. 2000; Cunningham et al. 2004). Potentially this might lead to interventions that could attenuate such emotional responses (see, e.g., Terbeck et al. 2012 on the use of propranolol in this context). Harris has criticized this proposal on the basis that racism is likely to involve a complex network of beliefs and not merely emotional reactions (Harris 2011). Although this is almost certainly true, it does not demonstrate that ingrained emotional reactions do not contribute to the tendency to hold stubbornly onto ill-founded beliefs in the face of the evidence. Attenuating such emotional responses might help the offender to assess the issues dispassionately and realize that his racist views are ill-founded (see also Douglas 2013a).

Delaying Gratification

Difficulties with delaying gratification may lie behind some individuals' tendency to break the law. Neuroenhancements could potentially help to rehabilitate criminals through enabling them to work out and implement strategies to delay gratification (see, e.g., Penney 2012).

Increasing the Ability to Focus on Relevant Issues

Recent studies suggest that individuals who score highly on measures for psychopathy may suffer from a kind of attention-deficit disorder which may help to explain their characteristic antisocial behavior (Newman et al. 2010). It seems that when presented with incentives for performing an action, these individuals lose sight of the reasons against performing the action. Neuroenhancements might enable these individuals to focus on all the relevant considerations (and in particular, the reasons against breaking the law).

Should Neuroenhancement of Offenders Be Prohibited Altogether?

This section will consider some concerns people may have about the neuroenhancement of offenders. It will argue that these concerns do not justify prohibiting such interventions, provided that offenders consent to them and that they are sufficiently safe and effective.

Neurointerventions Could Prevent Morally Desirable Behavior

In a recent article, John Harris argues that neurointerventions designed to diminish aggression may not be morally desirable (Harris 2011). He cites an example of an individual who attacked a terrorist who was about to detonate a bomb, thereby rescuing a plane full of people. According to Harris, if the rescuer had been given SSRIs to reduce his aggression, he might not have managed to save the plane.

Harris does highlight a genuine concern – moral understanding and morally motivated behavior are complex phenomena. Even the well-intentioned use of biomedical interventions risks causing undesirable consequences. However, when assessing whether offenders should receive such interventions, it is important to take into account the likelihood of the relevant scenarios occurring. In the case of many violent offenders, the risk that the intervention will prevent them from heroically rescuing a crowd of innocent people may seem relatively small compared with the risk that without the intervention, they will reoffend.

Neurointerventions Threaten Free Will/Autonomy

Harris (2011) has also argued that neurointerventions could deprive the offender of the ability to choose to do wrong – an ability that he claims is central to free will and moral agency (see also Matthews 2007).

It should be noted that this objection could only apply to neurointerventions that make it impossible to give in to temptation. However, few interventions would have that effect. Interventions that reduced the strength of some of the offender's antisocial urges increased the strength of competing desires to obey the law, or otherwise strengthened his capacity for self-control would not fall foul of Harris's objection.

Furthermore, it is doubtful that the ability to commit certain immoral acts is central to one's status as a moral agent. For instance, someone with a proper respect for the rights of women and children and with a very vivid appreciation of the horror of sexual abuse from the victim's perspective may be psychologically incapable of committing rape or acts of pedophilia. This inability would not undermine such a person's status as a moral agent.

If the offender's inability to commit certain acts is the result of his autonomous choice to receive neurointerventions (in the knowledge they would have that effect), then his inability should not necessarily be seen as an interference with his autonomy. His behavior post-intervention can be considered autonomous since it can be "traced" to his earlier autonomous decision (cf. Timpe 2011). Some offenders actively seek neurointerventions. It seems more respectful of their autonomy to offer them this option than to deny them the choice, especially in those cases where offenders have consistently requested neurointerventions over a period of time and their desire is based on full information and coherent reasons (see, e.g., McMillan 2013).

Nevertheless, certain interventions that have *globally* undermining effects on autonomy may be genuinely problematic. J.S. Mill, for instance, argued that it is impermissible to sell oneself into slavery (Mill 1909). By analogy, the individual might lack the authority to undergo neurointerventions that prevented reoffending by depriving him of the ability to make any further rational choices (cf. Bomann-Larsen 2013; McMillan 2013). Even if successful, this argument would only rule out the most extreme types of intervention.

Resisting Temptation Without Biomedical Interventions Is Intrinsically Valuable

Some writers have argued that neurointerventions could make it "too easy" to resist temptation, even if they did not eliminate the possibility of wrongdoing (Olsen 2006; Sorensen 2010). One rationale for this position is based on the value of effort itself. The attempt to address one's darker urges by reflecting on their source (e.g., in one's childhood) rather than opting for drug treatment might also lead to valuable self-knowledge.

Even granting that effort and self-knowledge are intrinsically valuable, that does not mean that *every activity* should be effortful or must generate self-knowledge. These goods are only two among many. Given that the offender's behavior can cause himself and others great harm, then surely the value of harm prevention must be given considerable weight when deciding whether interventions to address this behavior are permissible. Furthermore, even if one is primarily concerned with effort and self-discovery, *denying* an offender neurointerventions could interfere with these values. If the offender is constantly wrestling with violent or sexually abusive urges, then he may lack the time or energy to engage in other activities (e.g., charity work, the development of a talent, or relationships) that may require moral effort and may lead to self-knowledge (Levy 2006).

Neurointerventions Could Allow Offenders to Escape Their Just Deserts

Some retributivists might oppose offering neurointerventions as a condition of early release from prison on the basis that sentences should be based solely on the offenders' just deserts. Neurointerventions may render an offender non-dangerous, but this, it might be claimed, is no reason to release him if he has not yet paid the appropriate penalty for his immoral conduct.

There is not space within this article to defend a particular justification of punishment. However, it should be noted that many theorists believe that a legitimate function of the criminal justice system is to protect the public and to rehabilitate offenders. Certainly, in practice, most criminal justice systems give some weight to such goals, and are not solely concerned with retribution. Even on certain retributive views, there might be an argument for reducing an offender's

sentence if he volunteers to undergo a neurointervention. For example, the offender's request of a neurointervention might be seen as indicating his recognition of the unacceptability of his conduct (and as an attempt to prevent it recurring). This might merit a reduced sentence for similar reasons that an early guilty plea, or expressions of remorse, might be mitigating factors. On a communicative retributive view (e.g., Duff 2001) – according to which the criminal justice system should attempt to engage with dialogue with offenders and to bring them to repent their wrongful conduct and reform – neurointerventions might be seen as playing a complementary role alongside traditional punishments (see Shaw 2011). Certain neurointerventions might play this role if they could enable offenders to engage more effectively in dialogue and to empathize with their victims.

Arguments for Mandatory Neuroenhancement of Offenders

Most theorists who have written on this topic assume that the use of neurointerventions in rehabilitation programs could only be permissible if it were voluntary, without giving the possibility of mandatory interventions much attention. However, some jurisdictions currently subject offenders to compulsory biomedical interventions that have neurological effects. For instance, in certain American states, repeat sex offenders can be given mandatory chemical castration or can be forced to choose between surgical or chemical castration, both of which (as noted above) cause significant physiological and psychological changes including reducing sexual thoughts and desires (Harrison and Rainey 2013). The case in favor of involuntary neuroenhancement of offenders therefore merits further consideration. This section will attempt to put that case at its strongest. The next section will present the arguments against involuntary neurointerventions – arguments that, on balance, seem more persuasive.

Neuroenhancements May Be More Humane than Traditional Punishment

Most theorists believe that the state is entitled to subject offenders to punishment without requiring the offender's actual, explicit consent (cf. Ryberg and Petersen 2013a). Why should rehabilitation programs be treated differently? Theorists who oppose mandatory neuroenhancement are often motivated by concern for the offender's interests. However, it is possible to imagine that types of neurointervention may be developed that would cause the offender less suffering and deprivation of liberty than traditional punishment. Prisons are dangerous and depressing places that can leave offenders with permanent psychological and physical injuries. If safe and effective neuroenhancements were developed that allowed criminals to be quickly rehabilitated and returned to their communities, then it would seem more humane to compel offenders to undergo these interventions than to spend years in prison.

A Rational Offender Would Consent to Neuroenhancement

Some theorists justify punishment on the basis that, hypothetically, the offender would consent to it, if he were rational. For example, Benjamin Vilhauer (2009) has argued that society's treatment of offenders should be governed by rules that everyone would consent to from behind John Rawls's "veil of ignorance" (Rawls 2005). The veil of ignorance is a thought experiment that involves imagining oneself choosing the rules of society in accordance with rational self-interest, but without knowing what social position one will be allotted, including (as Vilhauer insists) whether one will be a victim or an offender. Decision-makers behind the veil of ignorance must therefore put themselves in the shoes of everyone affected by a social policy. This thought experiment is meant to exclude personal biases and ensure that the interests of all members of society are given equal weight. If certain neuroenhancements turn out to be safer and more effective than traditional punishment, then compulsory neuroenhancement might be in the interests of victims and perpetrators alike. If so, then the offender himself (provided he were wholly rational and imagined himself to be behind the veil of ignorance) would agree that neuroenhancement should be mandatory.

Offenders Forfeit the Right to Refuse Neuroenhancement

Alternatively, it might be argued that we should not be too concerned about protecting the interests of offenders. Various theorists claim that offenders, by committing a criminal act, forfeit their right not to be punished (e.g., Wellman 2012). It might be further argued that offenders also forfeit their right to choose whether or not to receive neuroenhancements that would address their offending behavior.

Potential Victims Are Entitled to Effective Protection

Julian Savulescu and Ingmar Persson (2008) have argued that if safe and effective biomedical moral enhancements were developed, then they should be compulsory for everyone. They believe this would reduce the chance that humanity would abuse powerful destructive technologies (e.g., nuclear materials and instruments of bioterrorism) – technologies that a rapidly increasing number of people will have access to in the future. Vojin Rakic (2013) opposes compulsory enhancement of the whole population, but suggests that it might be appropriate for certain repeat offenders, such as child rapists, whose release from prison would be dangerous. One way of specifically addressing Savulescu's and Persson's concerns might be the mandatory neuroenhancement of those who have already breached antiterrorism laws.

The Rights of Offenders' Families

A long prison sentence may separate offenders from dependent relatives, thus depriving children, partners, and elderly parents of emotional and financial support. If safe and effective neurointerventions were developed, allowing offenders to be quickly rehabilitated, then offenders could fulfill their familial obligations.

An Economic Argument

Prison is phenomenally expensive. It costs £40,000 to keep a single in-mate in prison in the UK for only 1 year (Adebowale 2010). (This is more expensive than educating a boy at Eton College for the same period.) For many offenders, prison is inadequate deterrent. According to recent Ministry of Justice Statistics for England and Wales, 11,000 offenders, who had each been jailed at least 11 times in the past, together were responsible for 50,000 offenses within a single year (Ministry of Justice 2013). If effective neurointerventions were developed, then their mandatory use in offender populations could generate massive savings. Such interventions could also benefit the economy by allowing offenders to re-enter the workforce. It might be thought that economic reasons are insufficiently weighty to justify compulsory neurointerventions. However, it should be remembered that our society is currently prepared to impose great burdens on individuals for economic reasons, e.g., withdrawing funding for potentially life-saving treatments.

Arguments Against the Mandatory Neuroenhancement of Offenders

The Power to Impose Mandatory Neurointerventions Is Too Easily Abused

There is already a vast inequality of power between the state and individual citizens. The state has the ability to use coercive force to deprive offenders of their property, cut them off from their friends, families, and communities, and to severely constrain their movements. Rather than being an argument for increasing the state's power still further, this should lead us to question whether it is justifiable to make the gap between the state and individual citizens even wider. If the authorities were able to impose mandatory neuroenhancement, this would give them a significant level of control over the individual's inner life. This obviously has potential for abuse, e.g., it could be used to suppress legitimate dissenters. By definition, it is wholly unacceptable to impose any form of coercive sanction on such dissenters. However, at least traditional methods of punishment do not interfere with these citizens' freedom of conscience to the same degree as mandatory neurointerventions and dissenters may use their time in prison as a form of protest.

During a substantial part of the twentieth century, several states in the USA had many discriminatory criminal laws, including a ban on interracial marriage (that particular law was not overturned until Loving v Virginia 388 US 1 (1967)). This great injustice would have been exacerbated if the authorities been able to force individuals convicted under such laws to undergo neurointerventions designed to decrease their attraction to members of a different race. It is not unrealistic to think that future legislators may enact unjust laws. (Indeed, even at present, it is quite likely that we have certain criminal laws which society will, in the future, recognize as unjust. Throughout history, there have always been certain norms in whose soundness people once had great confidence, but which have been overturned as society progressed.) Legislators need not even be thoroughly corrupt for such laws to be created – they may be well intentioned but misguided. If society were already well accustomed to the authorities' use of mandatory neurointerventions to rehabilitate justly convicted offenders, it would be that much easier for the authorities forcibly to impose such interventions on those convicted under unjust laws. We need to set limits on the state's power by ensuring that there is some sphere of individual liberty into which the state may never intrude. Whatever other liberties one may potentially "forfeit," an individual should, at least, be able to veto any biomedical interference with her own brain.

A Retributive Objection

The fact that state can force offenders to undergo traditional punishments does not imply that it has the right to force offenders to undergo neurointerventions (Cf. Ryberg and Petersen 2013a). On a retributive view, the state's right to sentence offenders to prison, community service, etc. stems from its right to punish. On Michael Moore's (1997) influential retributive theory, punishment is the intentional infliction of deserved suffering on moral wrongdoers, on the basis that such suffering is intrinsically good. However, most theorists agree that neurointerventions should not be viewed as punishment in the retributive sense. Neurointerventions are methods of rehabilitation, intended to protect society and/or to help offenders themselves to lead better lives. As Bomann-Larsen (2013) points out, to view mandatory neurointerventions as a form of retributive punishment would involve abandoning fundamental principles of justice such as the principle that punishment must not be "cruel or unusual." It would seem the height of cruelty to impose neurointerventions because of the suffering they could produce (e.g., the distress of having one's mind manipulated against one's will and any side effects these interventions might have).

As noted above, the most plausible reasons for employing neurointerventions are for the protection of others and/or to benefit the offender himself. There is a strong argument that the state's power to intervene for such reasons must be constrained by the need to respect the individual's status as an autonomous agent. If there were no such constraint, then the state could sacrifice individuals whenever this promoted the general welfare, or whenever *the state* judged this to be in the individual's best interests. Forcing an offender to undergo neurointerventions, without his

consent, would disregard his rational capacities and would arguably involve treating him as an object, as a being without human dignity (See section "Mandatory Neurointerventions Objectify Offenders", below). In contrast, a retributivist might argue that the state's right to force offenders to undergo traditional punishment already respects their autonomy, since it is intended as the deserved penalty for an autonomous action (not as a means of pre-empting future autonomous decisions to reoffend) and thus does not require explicit consent.

A Non-Retributive Objection

This section will now sketch an objection to mandatory neurointerventions that is very different from the retributive objection discussed earlier. The alternative line of argument that will now be developed should appeal to some of those who reject the idea that the suffering of the guilty is intrinsically good. Derk Pereboom (2001), for instance, believes that offenders' interests and preferences are of equal moral weight to anyone else's. Yet, he obviously acknowledges that serial rapists and murderers cannot simply be allowed to roam free. He does not claim that society has a general, unlimited right to sacrifice individuals for the overall welfare. Rather, he argues that society does have a right (similar to the right of self-defense) to protect itself from individuals who pose a serious threat to others. This right is subject to various constraints including a necessity constraint – the state should set back dangerous individuals' interests no more than is necessary to prevent them from harming others. He draws an analogy with quarantine. If society has the right to protect itself against carriers of dangerous diseases by subjecting them to quarantine, then it has the right to protect itself from dangerous offenders by incapacitating them. He argues that (like quarantine) the conditions of an offender's incapacitation should be humane and should still give weight to the offender's preferences. Without effective neurointerventions, constraining offenders' movements would often be the only humane and effective way of protecting society. In such circumstances, given society's right to protect itself, mandatory detention would be legitimate. However, Pereboom's view seems to imply that if safe and effective neurointerventions were developed, then society would lose the right simply to impose mandatory detention. Nor would it gain the right to impose mandatory neuroenhancement. Rather, it would show most respect for offenders' equal moral status to give them the choice between detention until they become non-dangerous, and, alternatively, neuroenhancement.

Thus, whether one takes a retributive position (like Moore's) or a radically non-retributive position (like Pereboom's), there are strong reasons, from within these perspectives, to oppose mandatory neuroenhancement of offenders.

Mandatory Neurointerventions Objectify Offenders

There are good reasons to resist any tendency to objectify offenders (reasons that are available to theorists regardless of whether they view offenders' moral status

from a retributive or a non-retributive standpoint). Offenders are already among the most despised members of society. People's desire to see offenders suffer often exceeds anything that could be morally justified, even on the most severe retributive view. There is a danger that feelings of disgust for criminals could lead society to lose sight of their humanity. It is therefore particularly important to have clear restrictions on the ways in which the state can treat them. The term "objectification" can be used in different ways. The conception of objectification that this chapter adopts is influenced by sociological discussions of the ways in which disfavored groups within society have historically been objectified or treated as "subhuman" (see, e.g., Reicher 2006). This kind of objectification typically involves creating a division between "them" and "us" that excludes the objectified group (cf. Shaw 2012). If offenders, unlike the rest of society, are subject to mandatory neurointerventions, then they are forced to relinquish something that many people regard as fundamental to their own status as persons – their control over their mental and bodily integrity. This would radically set criminals apart from the rest of society – leading us to categorize them as "the other" – as beings who lack basic rights and are largely outside the sphere of our moral concern. True, some of our basic moral rights, e.g., freedom of movement, are qualified. The right to freedom of movement does not provide immunity from state interference after one has committed a serious crime. However, there is a categorical difference between interfering with an offender's freedom of movement and forcibly interfering with the offender's mental and bodily integrity. Our right to mental and bodily integrity is more fundamental (and essential to human dignity) and merits even greater protection than our right to freedom of movement. Offenders cannot simply be said to "forfeit" their right to mental and bodily integrity without giving up something that is central to their status as persons.

The Voluntary Use of Neuroenhancement in Rehabilitation Programs

Informed Consent

It is important that offenders are given full information about the potential side effects and efficacy of neurointerventions. However, as Henry Greely (2008, 2012) points out, gathering such information may be far from straightforward. It is difficult to draw conclusions from animal models about the effects of brain interventions, since the human brain is very different even from the brains of closely related species, e.g., chimpanzees, let alone the brains of lab rats. Experiments on primates are also extremely ethically controversial. Usually, when a medical intervention is developed in order to treat a disease, information about its effects can be gathered from trials on volunteers who participate in the hope of benefitting from the treatment. However, since neuroenhancements are given to address antisocial behavior (i.e., largely for the benefit of people other than the recipient), volunteers may be much harder to find.

However, if an intervention for controlling offending behavior also has another clinical use, then a certain amount of data on side effects may already exist. For instance, testicular pulpectomy has been employed in certain countries (e.g., Germany) to help reduce sexual reoffending (see McMillan 2013). Some information about the side effects of this procedure is available since it is also an established treatment for prostate cancer. As noted above, SSRIs and propranolol may reduce violent and racist tendencies respectively. SSRIs are also used as antidepressants and propranolol is a treatment for hypertension and their use in this context has generated information about their side effects.

It might be thought that, in order to make a truly informed choice, the offender should also be provided with information about the risks of refusing treatment (e.g., statistical information about the mental health risks of remaining for a potentially longer period in prison). However, some might worry that if officials emphasized the risks of prison when offering neurointerventions, the state might be perceived as exploiting the fear of prison to "coerce" offenders into accepting neurointerventions (cf. McMillan 2013).

Voluntary Consent

If an offender is offered neuroenhancement as a condition of early release from prison, then he is faced with a choice between unappealing alternatives. However, this does not seem to preclude the possibility of giving voluntary consent to neurointerventions, provided that the offender is not dominated by a literally irresistible fear of spending a longer time in prison (Bomann-Larsen 2013). After all, patients are often considered capable of freely consenting, despite being faced with very hard choices, e.g., a choice between undergoing risky and disfiguring surgery to remove diseased tissue and, alternatively, refusing treatment and dying from their disease.

Threats and Inappropriate Offers

In order for consent to be normatively valid, more is required than minimal voluntariness (i.e., the absence of irresistible impulses) and adequate information. A valid consent to an offer of a biomedical intervention might plausibly be thought to have the following moral and legal effects: if such consent is given, then the person making the offer ("the offerer") has not wronged the person receiving the intervention ("the recipient") by providing that intervention. If the offerer were accused of having wronged the recipient, then the former could rely on the latter's consent as a defense. When thinking about whether valid consent exists, it is common to focus on the freedom of the person giving consent, i.e., the subjective sense of pressure she is experiencing and how restricted her alternatives are. However, if consent is to have the moral and legal effects just described, then it also makes sense to look at the conduct of the person seeking consent. It is well

accepted that a person's "consent" can be invalid if it were obtained by (nontrivial) threats to violate that person's rights. This is not because a person who is subject to such threats necessarily faces a harder choice or feels more pressure than the dying patient in the example given above. The victim's consent is invalidated because of the wrongful conduct of the party threatening to violate the victim's rights. The issuing of a threat of this kind seriously wrongs the victim and therefore, the activity that is "consented" to, as a result of that threat, also wrongs the victim. Bublitz and Merkel make a similar argument, rightly emphasising that a subjective, psychological sense of pressure will not automatically invalidate consent (Bublitz and Merkel 2009, 2013). However, they seem to endorse Feinberg's claim that wrongful threats invalidate consent because threats render consent involuntary (Bublitz and Merkel 2009, pp. 372–373; Feinberg 1987, p. 196). In contrast, I favor the view that wrongful threats/offers can invalidate a person's consent, even if the consent is voluntary. Voluntariness is one necessary condition for the validity of consent to a neurointervention, but the moral permissibility of the proposal to intervene is plausibly another, separate, requirement for the validity of consent (see Bomann-Larsen 2013). It is the latter requirement that is breached by wrongful threats.

If an offender were offered a neurointervention as a condition of early release from prison, it would be a mistake to construe his original prison sentence as a "threat" to violate the offender's rights. If this original sentence is a just response to his crime, then by definition, it does not violate his rights (Bomann-Larsen 2013). The offer of a neurointervention is a genuine offer. However, Bomann-Larsen argues that certain offers of medical interventions can also seriously wrong the other party and thus invalidate consent to such interventions. She cites Feinberg's (1986) example of a prison governor who offers to commute the sentence of a prisoner on death row if the prisoner participates in a medical experiment. The governor is abusing his position – he has no right to propose that the prisoner participate in such an experiment. He is taking unfair advantage of the prisoner's predicament. His offer wrongs the prisoner and arguably invalidates the prisoner's consent to the experiment. Note again that the key point is not the hard choice that the offender faces. In the example just given, the offender's alternatives are both very unappealing – death on the one hand and a potentially risky experiment on the other. However, as Bomann-Larsen points out, the governor's offer would still be wrongful if he presented the prisoner with an easier choice, e.g., "I will spare your life if you bring me tea every morning for 10 years." This offer is still wrongful, since the governor, qua governor, is not entitled to propose that the prisoner becomes his servant.

Similarly, Bomann-Larsen persuasively argues that the state can wrong an offender by offering him neurointerventions that are aimed at altering personality traits or private behavior that the state has no right to interfere with. The offender may be an untrustworthy friend, an unfaithful spouse, and an uncooperative colleague. But such traits or behavior are none of the state's business. In contrast, the state is entitled to seek to fix the problematic behavior for which the offender was convicted. Bomann-Larsen argues that, ideally, any intervention offered to offenders should be strictly necessary to address that behavior.

Ryberg and Petersen (2013a) raise the following objection to this necessity constraint. They point out that the state has a general duty to protect the public from all crimes, not just the one for which the offender was convicted. If, after the offender is convicted of one crime, a psychological evaluation reveals that he has a disposition to commit another type of crime, then they suggest that the state may have the right to offer him a neurointervention to address this latter disposition. In response, it is submitted that the state's duty to tackle criminal behavior must be subject to various procedural constraints. For instance, the state cannot subject an individual to punishment for a crime unless it is proved beyond reasonable doubt that he committed it. One justification for the beyond reasonable doubt standard is based on the kind of trust and respect the state should show to citizens as members of the moral community (Duff 2001). Rather than the default position being an attitude of suspicion, the state's relationship with citizens should begin with a strong presumption that citizens are morally well motivated (or at least that they do not violate the central moral norms underlying the criminal law). It should take strong evidence to rebut this presumption. Establishing beyond reasonable doubt that the offender has already committed a criminal act provides fairly strong evidence that the offender has a disposition to commit acts of this kind. Thus, it does not show disrespect, or distrust, to offer him interventions to address this disposition. However, it would be inappropriate to assume that the offender were liable to commit a range of other, unrelated crimes on the basis a psychological evaluation, rather than past behavior. The offender's conviction for a particular crime is not meant to be the starting point for a general investigation into his character and dispositions to commit unrelated crimes. That would also present too great an intrusion into individual liberty.

Conclusion

This chapter has critically discussed some of the main arguments for prohibiting the use of neurointerventions in offender rehabilitation programs and for the opposite position of making such interventions mandatory. Both of these extreme positions are ultimately unconvincing. If sufficiently safe and effective neurological techniques for addressing criminal behavior were developed, the best policy would be to offer them on a voluntary basis. In order for consent to such interventions to be genuine and valid, certain conditions must be met. Consent must, of course, be informed and voluntary. In addition, it is important to remember that the concept of "valid consent" (in a robust, morally significant sense) is closely bound up with the idea of respect. If the state is to cite the offender's consent as part of the moral justification for intervening in his brain, then it must ensure that when obtaining that consent, it did not act in an exploitative manner or overstep its authority, but instead that it respected the offender's status as a moral agent.

Future Directions

The development of neurointerventions with the potential to address offending behaviour is still in its early stages. More research needs to be done on the side effects and effectiveness of such interventions, including possible long-term side-effects. Ethicists will be a better position to deliberate about the acceptability of offering neurointerventions when the risks attached to such interventions are properly understood.

section is by Cordelia Fine and Fiona Fidler on ▶ "Sex and Power: Why Sex/Gender Neuroscience Should Motivate Statistical Reform" (Chap. 91). They describe how the current statistical method of null hypothesis significance testing specifically contributes to scientific error in sex/gender neuroscience. They suggest that sex/gender neuroscience may therefore provide a valuable model to motivate, on ethical grounds, statistical reform within the psychological sciences.

Characteristics

Feminist neuroethics uses gender as a lens to approach neuroethics, drawing on an ever-growing body of feminist theory and scholarship. Although there are many types of feminists and feminist theories, all consider gender to be an important analytic lens. All promote political, economic, and social equality of the sexes. And all agree that human beings live gendered lives in a social world that contains both explicit and implicit misogyny, sexism, and androcentrism. A feminist expectation is that addressing gender-based injustices will result in a better world for both women and men. Feminist theory often draws on and overlaps with the critical theories of other oppressed groups marked by, e.g., race, class, disability, or sexual orientation. The shared goal of such critical theories is a society free of oppression, bigotry, and group-based harms of all sorts.

There are several feminist concerns related to neuroethics. One is the degree to which neuroscientists treat the male brain as the "standard" brain and the female brain as the "other." Another is the potential for sex/gender bias, if not all-out sexism, in sex-difference research and how best to promote research that is less biased. Some feminists have specific concerns over some neuroscientists' claims that there are innate sex-based differences in our psychologies. And a broader set of questions of possible concern to feminist scholars includes the following: To what degree can or should scientific research including neuroscientific research be "value-neutral" and "objective"? What research questions are and are not posed, and why? What hypotheses are and are not tested? Whose interests are and are not promoted by various neuroscientific research programs?

Outstanding books that take a feminist approach to neuroethics include *Sexing the Body*: *Gender Politics and the Construction of Sexuality* by Anne Fausto-Sterling (2000), *Delusions of Gender*: *How Our Minds*, *Society*, *and Neurosexism Create Difference* by Cordelia Fine (2010), *Brain Storm*: *The Flaws in the Science of Sex Differences* by Rebecca M. Jordan-Young (2010), and *Neurofeminism*: *Issues at the Intersection of Feminist Theory and Cognitive Science* edited by Bluhm et al. (2012).

This feminist section of the *Handbook of Neuroethics* contains four articles. The first is by Robyn Bluhm on ▶ "Feminist Philosophy of Science and Neuroethics" (Chap. 88). Bluhm maintains that feminist philosophy of science can provide theoretical and methodological resources to address questions posed within neuroethics. These resources can be applied to contemporary research on sex/gender differences as well as to many other areas of neuroscience under ethical

scrutiny. After briefly surveying recent feminist critiques of neuroscience research on sex/gender differences, she demonstrates how two main themes in feminist philosophy of science – feminist standpoint theory and feminist empiricism – drew on this research to develop new theoretical approaches to philosophy of science. Finally, she examines how some of the key features of feminist philosophy of science might apply to research in neuroscience.

The second article in this section is by Peggy DesAutels on ► "Feminist Ethics and Neuroethics" (Chap. 89). DesAutels focuses on the branch of neuroethics devoted to the neuroscience of moral judgments and behaviors. She takes a feminist approach to this particular branch of neuroethics. She examines if and to what degree there are sex/gender differences in moral judgments, behaviors, and traits and asks: If there are apparent differences, what are the most likely causes? She argues that most differences are attributable not to sex-based brain differences between men and women, but to distinct and persistent types of psychologies found in members of oppressing and oppressed groups.

The third article is by Anne Jaap Jacobson entitled ► "A Curious Coincidence: Critical Race Theory and Cognitive Neuroscience" (Chap. 90). Jacobson examines implicit bias and the degree to which it can be changed. Her focus is on bigoted racial bias, but she is motivated by concerns for gender bias as well. She draws on critical race theory and neuroscientific investigations of biased judgments to address the questions: (1) To what degree are those who hold harmful implicit biases morally responsible for their biased actions and attitudes? (2) To what degree and using what strategies can harmful implicit biases be mitigated?

The fourth and final article in this section is by Cordelia Fine and Fiona Fidler on ► "Sex and Power: Why Sex/Gender Neuroscience Should Motivate Statistical Reform" (Chap. 91). In this article, they briefly review the benefits of the estimation statistical approach as a means to producing reliable information about nature. They then describe how the current statistical method of null hypothesis significance testing specifically contributes to scientific error in sex/gender neuroscience. They highlight the potential social harm that can arise from such errors in this area of research and suggest that sex/gender neuroscience may therefore provide a valuable model to motivate, on ethical grounds, statistical reform within the psychological sciences.

88 Feminist Philosophy of Science and Neuroethics

Robyn Bluhm

Contents

Abstract

As a recognized subdiscipline of applied ethics, neuroethics is quite new; however, ethical analyses and critiques of neuroscience have a long history. A significant proportion of these critiques have come from feminists, in response to research that aimed to uncover differences in the brains of women and men and often to use these differences to support political claims about women's place in society. This entry surveys these feminist critiques and looks at the potential for recent work in feminist philosophy of science to contribute to neuroethics. Because it addresses the appropriate role for values in scientific research, feminist philosophy of science can provide useful tools for the analysis of sex/gender difference research and also for a variety of other topics of interest to neuroethicists.

Introduction

As a recognized subdiscipline of applied ethics, neuroethics is quite new; however, ethical analyses and critiques of neuroscience have a long history. A significant proportion of these critiques have come from feminist scholars, in part because of (and focusing on) neuroscience research on sex/gender differences. Yet, to date, there have been relatively few attempts to develop an explicitly feminist approach to neuroethics. Peggy DesAutels (2010) has called for neuroethics to pay more attention to feminist work on sex difference research. Both Deboleena Roy (2012) and Katrin Nikoleyczik (2012) have shown that work by feminist science studies scholars is very relevant to neuroethics. This paper does the same for feminist philosophy of science in the analytic tradition. Feminist philosophy has been an active area of research for nearly three decades, and it was inspired, in part, by feminist work that criticized sex/gender difference research in neuroscience and psychology. The field has now developed to the point where it can provide theoretical and methodological resources useful for analyzing questions addressed by neuroethics. These resources can be applied to contemporary research on sex/gender differences but also apply equally well to many other areas of neuroscience that have prompted ethical scrutiny.

This paper will begin with a brief survey of some feminist research that critically assesses neuroscience research on sex/gender differences. (As will be discussed later in the paper, there is debate over the extent to which differences between women and men should be attributed to sex or to gender. The compound term indicates that there is no way to settle this debate (see also Kaiser (2012)) It then shows how two main themes in feminist philosophy of science – feminist standpoint theory and feminist empiricism – drew on this research but went well beyond these critiques to develop new theoretical approaches to philosophy of science. Although these two forms of feminist philosophy were originally in tension with each other, they have always shared much common ground and have converged over the years. The final section of the paper highlights some of the key features of feminist philosophy of science and show how they might apply to research in neuroscience.

Feminist Critiques of Neuroscience

Feminist scientists and science studies scholars have documented numerous cases in which prevailing concepts of the nature of women and of men have shaped scientific research, particularly in biology and the social sciences. Because neuroscience promises to explain so much about our characters and behaviors, it has been a key area of research on sex/gender differences, attractive to those who sought to explain – and sometimes to justify – the different places in society occupied by women and by men. This section briefly describes some of this research and shows that it raises important questions for philosophy of science.

While biological explanations of women's inferiority to men date back at least to Aristotle's work (see Tuana (1993) for a discussion of this history), the second half of the nineteenth century saw a large increase in research on sex differences. It also

marked the "first wave" of feminism in the United Kingdom and the United States. Women were demanding the right to vote and, more generally, to play a greater role in public life. Their political activity threatened the existing social order, which was based on a sharp distinction between the roles of women and of men; while men were appropriately concerned with politics, commerce, and science, women's place was in the home.

The different roles of women and men had largely been taken for granted as the being result of natural differences in the characteristics and abilities of each sex. Now that the roles were being challenged, however, it became important to demonstrate that they really were the result of such natural differences. Scientists began to investigate the differences between women and men. Janet Sayers surveys research in the late nineteenth century that was undertaken specifically in order to demonstrate that, owing to women's frailty, higher education would damage their health and fertility, thus also threatening the future of the human species (Sayers 1982, Chap. 2).

Elizabeth Fee has traced the attempts of craniologists to show that women's intellectual inferiority was the result of differences between their brains and men's. Craniologists, as their name suggests, actually measured the skull, rather than the brain, but contemporary theory said that because the skull "formed a faithful cast of the underlying brain. . .measurement of crania could therefore be substituted for direct measurement of the brain" (Fee 1979, p. 420). Demonstrating that women's skulls were smaller would therefore provide a biological explanation for their inferior intelligence and thus both explain and justify their exclusion from public life.

This project, however, proved to be more difficult than anticipated. Fee documents the many measurement techniques that craniologists used to try to demonstrate the inferiority of female skulls and the equally many failures to find a clear sex difference. Scientists looked for absolute size differences, size differences relative to overall body size, and differences in the relative size and shape of various parts of the skull. All of these approaches failed to show the difference that scientists sought. Yet scientists never questioned the hypothesis that they were attempting to prove that women's skulls would provide evidence of their intellectual inferiority. Nor did they question the more general hypothesis that women were less intelligent than men. Fee notes that "the whole enterprise thrived despite annoying setbacks; as one [measurement] index failed to measure up to expectations, another appeared, claiming to hold the solution all earlier problems" (p. 427). Eventually, the entire science of craniology "collapsed under its own weight" (p. 432) and was abandoned.

Fee's research on this era was conducted in the 1970s, a time at which second-wave feminism was leading to women's increased participation in the workplace and fewer people would overtly espouse the belief that women are intellectually inferior to men. Yet beliefs in the different strengths and abilities of women and men were still common, and still used to justify women's exclusion from certain fields, and once again scientists were busy trying to find a biological basis for those differences. Just as Fee's historical research uncovered sexism in nineteenth-century scientists, work by her contemporaries in the biological and social scientists showed that

similar assumptions about differences between women and men informed scientific work on sex differences in the 1970s and 1980s.

In fact, this period was an especially busy one for neuroscientists interested in sex/gender differences. In her critique of biological theories of sex differences, Ruth Bleier links this phenomenon directly to social changes, noting that "[a]s social movements threaten the social order, it is a recurrent phenomenon that corresponding scientific theories emerge that implicitly defend the *status quo*" (1984, p. vii). Like the nineteenth-century craniologists, Bleier's contemporaries were informed by the social background within which their research was conducted.

In some ways, the neuroscience research conducted in the middle of the twentieth century is shockingly similar to that of the previous century. During the 1980s, there was a spate of research examining the possibility that there were sex differences in the corpus callosum, a bundle of nerve fibers connecting the two hemispheres of the brain. These differences were hypothesized on the basis of a then-current theory that suggested that men's brains were more "lateralized" than those of women so that the left and right hemispheres operated relatively independently. Since women's brains were more closely connected, the hemispheres operated in tandem. Differences in lateralization were supposed to explain the (supposedly) different strengths of women and men, such as women's greater verbal ability and men's superior visuo-spatial skills. Anne Fausto-Sterling surveys this research on the corpus callosum and finds that it is in many ways similar to the craniology research of the previous century. Because this brain structure has a complex shape, there are many possible ways to measure it and scientists appear to have tried them all, yet "no matter how they carve up the shape, only a few researchers find absolute sex differences in CC area. A small number report that males and females have differently shaped corpus callosums. . ., even though the shape does not translate into a size (area or volume) difference" (2000, pp. 130–1). Yet scientists continued to debate whether there was a difference. Fausto-Sterling concludes that the longevity of the debate "speaks to how entrenched their expectations about biological differences remain" (p. 145).

Despite the similar methods and tactics used in both of the eras of research I have described, there are also important differences between them. One such difference is that the more recent period included an explicit debate about the "naturalness" of any differences found between the sexes. While in the nineteenth century, this was taken for granted, it is now hotly contested. Bleier ties this debate to political changes: "In the face of the contemporary vigorous resurgence of the women's movement and feminist scholarship, biological determinist theories have become a conspicuous part of our scientific and popular cultures" (1984, p. vii). Similarly, Sayers (1982) and Birke (1986) provide examples of the use of scientific research to defend conservative political positions. In general terms, biological determinism says that what we are is an inevitable result of our biology. When it comes to sex/gender differences, the implication of biological determinism (which, as noted above, is sometimes made explicit) is that the different social positions occupied by men and women are a direct and inevitable result of biological differences.

One key aspect of feminist thought during this period was the idea that the biological and psychological differences between women and men were

not inseparable. The former were assigned to the category of "sex" and were acknowledged to be natural, biological differences, but the latter – reflecting the different traits and abilities associated with each sex – were the result of the social environment. In other words, physical differences between women and men were thought to be irrelevant to differences in psychological and behavioral characteristics. Rather, these are the result of being raised in a particular social environment that included expectations about appropriate behavior for each sex. These latter characteristics were subsumed under the label of "gender" as opposed to sex. Distinguishing between biology and society, between sex and gender, was intended to undercut biological determinism. As Anne Fausto-Sterling explains, feminists distinguishing between sex and gender believed that "it was social institutions, themselves designed to perpetuate gender inequality, that produced most of the differences between men and women" (2000, p. 638).

Yet almost as soon as it was established, the distinction between sex and gender came under attack, not just by biological determinists but also by feminists who questioned the "naturalness" of physical, sex differences, arguing that they, too, were at least in part a product of differences in the way that girls and boys were raised and women and men lived. For example, differences in muscle mass and development were only partly the result of different hormone levels. They also occurred because boys were encouraged to be active and play sports, while girls were taught to prefer quieter, more sedentary games.

The distinction between innate influences on biology and the effects of experience was recognized as being particularly unclear when it came to the brain. Anatomical differences, for example, those in the corpus callosum, could be the result of a hardwired developmental program, as the biological determinists would have it. But it was also possible that the environment played an important role in shaping the structure of the brain. Developmental neurobiologists were learning how much of brain development occurred after birth and just how responsive the developing brain was to experience. Since boys and girls begin to have different kinds of experience from birth, it is not surprising that their brains develop differently. Nor were these arguments dependent merely on a vague appeal to cultural factors; accounts of environmentally influenced brain development drew heavily on neuroscience research. Anne Fausto-Sterling draws on developmental systems theory to outline the ways in which biology and the social environment might interact. She notes that merely *finding* biological differences in the brains of women and men does not show that those differences are an inevitable result of different (innate) developmental trajectories. They also are likely to reflect the different social environments in which girls and boys are raised. We know that there is a great deal of postnatal development of the brain and that this development is sensitive to the environment, so it is not unlikely that differences in the social environment will affect the brain. Fausto-Sterling draws the conclusion that "if differential social experience produces differences in brain anatomy and thus in brain function, later experiences would then be interpreted and integrated by a differently functioning brain" (p. 125).

One possible response to disagreements about the relative contributions of "nature" and "nurture" to observed differences in the brains of women and of men might be that we need to collect more data, that eventually scientists can amass evidence that conclusively supports one side or the other of the debate. This turns out not to be the case; one of the key insights of philosophy of science has been that any amount of data is always consistent with more than one theoretical explanation. The problem of underdetermination, as this point is called, means that scientists need to go beyond the data in choosing one theory over another. This does not mean that "anything goes" or that it is never possible to justify the choice of one theory over another. It simply means that scientists always draw on other considerations when interpreting data or developing theoretical explanations of phenomena. One type of consideration that informs their choices is epistemic values such as simplicity, explanatory breadth, and consistency with other theories in related domains. The second type of consideration, which is often only an implicit influence on scientists' choices, is background assumptions about the nature of the phenomenon being studied. In the case of research on sex/gender differences, background assumptions about the extent to which brain development is responsive to the environment influence the interpretation of experimental data. For example, recall the research discussed above on sex differences in the corpus callosum. Bell and Variend (1985) conducted a study in which they examined this structure in young children and found no sex/gender differences, despite the fact that some researchers had found such differences in adult brains. Those who are inclined to believe that sex/gender differences in the brain are largely a result of environmental differences would point to this study as evidence for their claims. But those who think that sex/gender differences are biologically determined would say that the differences that eventually emerge are the result of distinct (innate) developmental programs for each sex, something like the changes that emerge at puberty. Background assumptions about the source of sex/gender differences influence the way that people interpret the available evidence, biasing them to one interpretation or the other.

But science is not supposed to be biased; it has traditionally been assumed. Good science is thought to be objective and impartial. After all, part of the criticism leveled against neuroscientists by the feminist scholars discussed above was that their sexist beliefs, or at least their commitment to the existence of sex differences (whatever their origin), had a negative influence on their science. And part of the criticism raised against feminist science and feminist science studies is that "wishful thinking" about equality or background commitments to gender equality would lead to feminists' ignoring evidence that did not support their views.

It is here that feminist philosophy of science can make an important contribution to neuroethics; one of the main concerns of this area of research has been to clarify the ways in which science is – and should be – influenced by values. The next section provides some background about the origins and development of feminist philosophy of science and then turns to some of its key insights.

The Development of Contemporary Feminist Philosophy of Science

Much of the feminist criticism of neuroscience described above was conducted by feminist scientists who were themselves active researchers in the fields they critiqued. They therefore had a detailed knowledge of the methods and theories they discussed. In her discussion of emerging work in feminist philosophy of science, Sandra Harding calls their work "spontaneous feminist empiricism," which "arose as the 'spontaneous consciousness' of feminist researchers in biology and the social scientists who were trying to explain what was and what wasn't different about their research process in comparison with the standard procedures in their field" (Harding 1993, p. 51). This criticism was a form of empiricism, according to Harding, because it accepted certain basic characterizations of science that were accepted both by scientists and by the majority of philosophers of science of that time. Harding characterizes empiricism as being dedicated to the belief that science, or at least good science, is value-free. The social identity and the personal values of scientists would therefore be irrelevant to science. What mattered were criteria like the success of predictions and the ability of theories to provide a relatively simple explanation for a broad and diverse range of phenomena. Harding further characterizes spontaneous feminist empiricism as being concerned with case studies of bad science, believing that "sexism and androcentrism are social biases correctable by stricter adherence to the *existing* methodological norms of scientific inquiry" (Harding 1986, p. 24, emphasis added). In other words, the androcentric science critiqued by Fee and by Fausto-Sterling was the result of science's failure to live up to its own standards.

While Harding acknowledged the contributions to feminist aims that were made by spontaneous feminist empiricism, her own preference was for a critical approach that took greater account of the social environment within which science was practiced. As noted earlier, traditional empiricism in philosophy of science viewed the products of scientific work as being value-free. While scientists' personal interests and biases could inform the early stages of their work, the nature of the scientific method meant that these values were winnowed out of the final theory. This view was reflected in the traditional distinction between the context of discovery, which focuses on how theories are generated and the context of justification, which looks at how theories are tested. By contrast, Harding preferred a form of feminist standpoint theory, which emphasizes the pervasive influence of the social organization of scientific practice on scientific theories. Rather than seeing science as ultimately based on careful, neutral observations and logical argument, feminist standpoint theory analyzed science as a social practice in which members of social groups that have been traditionally excluded or marginalized can offer "a morally and scientifically preferable grounding for our interpretations and explanations of nature and social life" (Harding 1986, p. 26). Through political action, women and other marginalized groups can come to recognize both their distinctive social position and the advantage that that position confers. Harding contrasted this explicitly social and political approach to understanding science with that taken by

spontaneous feminist empiricism. Whereas the latter focused, not on changing science as a whole but on exposing cases of bad scientific research, standpoint theory aimed to replace androcentric methods and approaches to evidence with a more adequate account based on the standards suggested by women's experiences.

However, the distinction between spontaneous feminist empiricism and standpoint theory soon needed to be revised to reflect theoretical developments in feminist philosophy of science. At the same time that feminist standpoint theory was being developed, other feminist philosophers of science were also developing theoretically sophisticated forms of feminist empiricism that took into consideration both the political concerns of standpoint theory and the emphasis of traditional philosophy of science on standards for the adequacy of evidence.

Philosophical feminist empiricism, as exemplified in work by Helen Longino (1990, 2001) and by Lynn Hankinson Nelson (1992), differed from both traditional empiricism and spontaneous feminist empiricism in that it recognized that social values and interests play a role in science but continued to emphasize the fundamental importance of empirical criteria in choosing and testing scientific theories. It also recognizes the importance of epistemic values that are conducive to the empirical success of science, such as those discussed above (simplicity, explanatory power, etc.), though Helen Longino (1996) has developed a distinct set of feminist epistemic values that may sometimes be in tension with the more traditional list. While Harding does not emphasize this point, both Longino and Nelson also emphasize (in different ways) that knowledge must be analyzed at the level of the scientific community, rather than that of the individual scientist.

Although both philosophical feminist empiricism and feminist standpoint theory recognized the social nature of scientific knowledge and the inescapable role of values in science, some tension remained between them. Harding argued that feminist standpoint theory was the best way to challenge the traditional empiricist (and value-free) conception of science because of its more radical challenge to scientific methods and its emphasis on the influence of social location (and of the standpoint to which a social location might lead) on knowledge. She also argued that the implication of spontaneous feminist empiricism, which followed traditional empiricism, the social identity of scientific inquirers was "irrelevant to the 'goodness' of the results of research," sat uneasily with claims that a feminist approach to science would reduce instances of scientific bias. By contrast, Nelson worried that standpoint epistemologies, by positing an "epistemological chasm between feminists and nonfeminists" so that "there are things one group can know and another cannot know" (1994, p. 41), gave up any hope of finding an empirical common ground.

These disagreements are important to the history of feminist philosophy of science, but they should not be overestimated. It should be noted that in developing her defense of standpoint theory, Harding contrasts it mainly with spontaneous feminist empiricism and simply notes that "[i]t would be an interesting and valuable project to contrast in greater detail these important philosophical feminist empiricisms and/with feminist standpoint theory" (1986, p. 52); she does not undertake this latter project. More recently, Kristen Intemann (2010) and Elizabeth Potter (2006) have argued that developments over the past two decades in both

(philosophical) feminist empiricism and standpoint theory have brought the two approaches closer together. Intemann suggests that adherents to each view may have misrepresented the other, and that, in reality, “the main tenets of standpoint theory are far closer to those of feminist empiricism than proponents of either view have been willing to admit” (Intemann 2010, p. 206). She also notes that people working in the two different traditions also modified and clarified their views in response to criticism from the other side. It is perhaps best to view the two approaches as developing over time and as coming closer together as they did so. The two strands of feminist philosophy now differ mainly in emphasis, with standpoint theory focusing on the importance of social location and standpoint in shaping science and feminist empiricism emphasizing the importance of judging theories by their empirical successes, i.e., by their ability to make successful empirical predictions.

Some Central Insights of Feminist Philosophy of Sciences

Despite these differences in emphasis, there are a number of areas of agreement between feminist standpoint theory and feminist empiricism, and these can be taken to be core commitments of feminist philosophy of science.

The Role of Values in Science

As Elizabeth Potter (2006) notes, much of feminist philosophy of science starts from an examination of the relationship between science and values. In particular, feminist philosophers emphasize that science is shaped by various kinds of values (social, political, epistemic) at all stages of inquiry. Remember that the traditional empiricist approach to philosophy of science held that values were eliminated in the process of justifying theories; failure of this process meant that the resulting theory was an example of bad science.

By contrast with traditional empiricism, feminist philosophers viewed the influence of values on science as inescapable, and discussion of this problem has been one of the main areas of research in feminist philosophy of science. This meant that it was impossible to just dismiss the kind of science critiqued by the early (spontaneous) feminist empiricists as bad simply because it reflected social values. Instead, there had to be a way to differentiate between legitimate and illegitimate influences of values in science. Elizabeth Anderson (2004) has argued that values exert an illegitimate influence on scientific research when they drive the research to a predetermined conclusion. The craniologists whose work Elizabeth Fee examined looked for evidence to support their social beliefs about the relative intelligence of women and men and also thought that this evidence could be supplied by finding differences in the sexes’ skulls. Their unwillingness to give up their scientific hypothesis and the pattern of reformulating the specific changes they expected to see are evidence that their values pushed their research to the only conclusion they would accept.

This type of influence also occurs in contemporary research. For example, functional magnetic resonance imaging (fMRI) studies that look at (or for) sex/gender differences in responses to emotional stimuli generally start from the simple claim that women are more emotional than men, despite the complex and equivocal nature of much of the psychological literature on sex/gender differences in emotion, and look for differences in brain activity to explain these purported psychological differences. Despite the lack of clear evidence of differences in many of these studies, the authors always interpret their results in such a way as to support their original hypothesis of differences in brain activity (Bluhm 2012, 2013). Here again, the conclusion of the research appears to have been determined even before the study was conducted.

Although this research is clearly influenced by beliefs about gender and gender differences, its focus on differences may also be due in part to the difficulty of publishing "negative" results (i.e., results that show no difference between groups). This is another example of the way in which values determine the way science is conducted. Here, the values are not political, but they have a strong influence all the same. Moreover, even though the values themselves are not political, they have political consequences, since they lead to the conclusion that there are sex/gender differences.

A closer look at these studies shows that their very design makes it easy for researchers to find *some* sort of brain activity difference to talk about. Because the hypothesis being examined in these studies is that there are brain activity differences either "somewhere" in the brain, or in particular areas previously associated with emotion processing, any difference in observed brain activity can be taken to support the claim that differences in emotionality can be explained by differences in brain activation. This area of research has to develop more sophisticated models of emotion processing in order to provide clear evidence for the claim that women and men process emotional stimuli differently (Bluhm 2013). When hypotheses appeal only to vague activity differences, any difference can be taken in support of a sweeping claim regarding psychological differences. This does not mean that the researchers should not have conducted research on sex/gender differences in the first place, but it does mean that they should have been more open to disconfirming evidence and should have designed their studies so that their hypothesis was not confirmed by just about *any* evidence.

Though in fact, given how *much* disconfirming evidence there tends to be in sex/gender difference research, it is not unreasonable to ask why researchers are still working in this area. One possible reason is that sex/gender differences in emotion processing may have practical implications. Many of the fMRI studies I examined note in the introduction that women are much more likely than men to experience depression and suggest that this may be due in part to sex/gender differences in emotion processing. They often further suggest that a better understanding of emotion processing may lead to improved treatment of depression. Here is another example of the influence of values in science. Because scientists are encouraged – and even required by some funding agencies – to address the possible practical applications of their work, they often resort to speculation in cases where there is not direct potential

applicability. (This often occurs, as well, in work using animal models, which may indeed result in important knowledge, but which is not directly applicable to humans).

Yet, in fact, the researchers do not tend to take these issues into consideration in designing their studies, perhaps by including participants with depression, or attempt to incorporate neuroimaging studies that do look at brain activity in depression in their discussion of their results. It does not seem, then, that there is an honest attempt to address potential practical implications, so the research is clearly not motivated by these problems. Rather, as Fausto-Sterling said á propos of research on the corpus callosum, the persistence of this line of research seems to be evidence only of researchers' commitment to the belief that sex differences exist. And as with the other research I have surveyed, this belief persists despite any number of studies that fail to show clear sex/gender differences.

This brings us to a second aspect of Anderson's discussion of science and values. As noted above, Anderson suggests that values play an illegitimate role in science when they push research to a predetermined conclusion. This may be a sign that the values in question are held dogmatically (albeit possibly unconsciously) and scientists thus fail to change them in the face of evidence to the contrary. The belief (which also reflects political values regarding the existence of sex/gender differences) that "women are more emotional than men" may simply be held dogmatically; it appears to be held in a fairly unsophisticated form despite the lack of clear evidence to support it. Anderson emphasizes that just as science is shaped by values, values should be also responsive to empirical evidence. In cases where values are responsive to evidence, we can expect that scientists whose research does not show promising results will look for other avenues to investigate. This does not seem to happen with research on sex/gender differences.

Objectivity

A second area in which feminist philosophy has made important contributions is in understanding the social nature of science and its implications of this sociality for objectivity. Here again, we can start from the question of what sorts of values should play a role in science. If we take "objective" to mean value-free, or neutral, then it would appear that science can never be objective. But this conclusion is too quick. Since different individuals and different groups have different values, feminist philosophers of science have argued that science becomes more objective as *more* values are added to it. Fee's craniologists all shared the same basic (sexist) values, so their way of understanding the phenomenon they were studying went unchallenged (see also Okruhlik (1994)). Including researchers with different approaches and values can therefore help researchers to design better experiments, for example, by sharpening their hypotheses or qualifying their conclusions more carefully. For example, in the case of the fMRI research that I looked at, discussed above, the researchers may have designed better experiments if they had consulted with social psychologists, who study just how complex and nuanced emotional

experiences and expression can be and the extent to which sex/gender differences depend on environmental variables (see, e.g., Brody 1999).

The most influential discussions of objectivity in feminist philosophy are those offered by Helen Longino and by Sandra Harding. Both emphasize that incorporating diverse viewpoints into scientific research will provide a better, more objective, understanding of the phenomena being studied. Harding's "strong objectivity," which is based in standpoint theory, emphasizes the need to start from the perspectives of those who have historically been excluded from science and also the need for researchers to engage in critical examination of how their own social location influences their research (1995). Longino's critical contextual empiricism focuses on developing norms for scientific inquiry that promote objectivity by increasing the possibility that background assumptions shaping the research will be recognized and debated. These norms are: the existence of public venues for science criticism, uptake of criticism by the scientific community, shared public standards by which to evaluate scientific methods and claims, and tempered equality of participants in the scientific discourse (Longino 1990, 2001). Both theories emphasize that diversity in scientific communities is the best way to prevent the illegitimate influence of values on scientific research.

While Harding, in particular, emphasizes the importance of diversity of social groups or standpoints, it is also especially important in an area like neuroscience to incorporate diversity of *scientific* viewpoints. Relevant disciplines may include a number of subfields of psychology, sociology, linguistics, anthropology, computer science, and statistics, depending on the particular question being addressed. Because the brain is studied at a variety of biological levels and because the field of cognitive science was self-consciously founded as an interdisciplinary endeavor, there is a rich set of resources available for scientists to enable them to increase the objectivity of their research. Longino's norms may help to prevent the problem noted above, in which neuroimaging researchers did not work with social psychologists to clarify their hypotheses about sex/gender differences in emotion.

"Studying Up"

A third aspect of feminist philosophy of science, related to the issues of objectivity discussed above, is its insistence that research on social groups must start from the perspective of members of that group. The need to "study up" from the vantage point of oppressed groups is one of the key distinguishing features of standpoint theory, though feminist empiricists have also come to acknowledge it. Due to social differences between many scientists and the groups they study, scientists' understanding of the phenomena they are investigating may differ from that of the people they study, with the result that the research provides only a partial or skewed perspective on what is going on.

An example of research that was explicitly based on feminist principles is Gillian Einstein's work on the neurological effects of female genital circumcision/mutilation/cutting (FGC). Einstein was interested in the effects of this procedure on the central nervous system and on the body as a whole but also in the experiences of women who had undergone the procedure. She worked with a group

of Somali immigrants in Toronto, Ontario; these women not only were research participants but were also involved in designing the study. Upon consultation with this group, Einstein chose to use a combination of qualitative and quantitative methods, because neither on their own were able to address the range of questions she was interested in answering. As a result, she was able to investigate the physical effects of FGC on the nervous system and on the rest of the body, as well as the women's experiences of life after FGC (which were influenced by their knowledge that the practice is disapproved of in their new country).

Einstein draws on her experience planning and carrying out this research to develop a number of "guideposts" for feminist neuroscience practice, which include commitments to the kind of reflexivity demanded by strong objectivity; to considering research participants as partners; to understanding variability instead of focusing on averages; and to approaching a problem from multiple perspectives (Einstein 2012, pp. 166–168). It is important to recognize that this approach is not just a reflection of feminist political commitments but that it is also a better approach from an *empirical* perspective, since it provides a more adequate understanding of the phenomena being studied than research that does not use these guideposts.

Beyond Research on Sex and Gender

The previous section summarized some of the central insights of feminist philosophy of science and showed how they apply in both criticisms of neuroscience research and developing better research projects. This section briefly describes some ways in which these insights can apply in areas of neuroscience that are not explicitly concerned with sex/gender differences or with women's biology.

A number of debates in neuroethics might be better understood if we pay close attention to the kinds of assumptions that researchers make about the nature of the phenomenon they are studying, about the best methods and techniques to use in their research, and about how their research fits with other areas of investigation. One obvious extension of work in feminist philosophy is to take what we have learned from studying research on sex/gender differences and apply it to other areas in which two or more groups are compared, such as clinical neuroimaging, research on neurodevelopment and aging, and pre-post studies that examine the effects of learning or of other interventions. There are also other areas of "applied ethics" where feminist philosophy of science may provide useful tools, including debates over neurocognitive enhancement, lie detection, the use of brain-computer interfaces, and the use of pharmaceutical interventions to alter memory (Hurley 2010). At a more abstract level, neuroethics also investigates the effects of research in neuroscience on questions that have important implications for our self-understanding, such as questions about free will and moral responsibility, personal identity, and the possibility of "mind reading" using neuroimaging technologies. All of these are complex concepts, and feminist philosophy of science may be helpful in clarifying the ways in which scientists' preconceptions about these questions shape their research.

Finally, any research that explicitly deals with social questions or focuses on particular groups may benefit from feminist analysis. The idea of "studying up" means that the viewpoint of participants should be included in designing and conducting neuroscience research, which may mean including questions that are important to patients in clinical studies or collecting phenomenological data in order to learn how study participants interpret the task (Womack and Mulvaney-Day 2012; Gallagher 2012). And, finally, a feminist approach will also be useful for research in social cognitive affective neuroscience (SCAN), which needs to frame questions that can have clear political implications in a way that is methodologically tractable but that avoids oversimplifying complex issues and questions. Specific topics here include the nature of social stereotypes, the evolution of emotion and of moral reasoning, and the relationship between psychopathy and theory of mind, as well as consideration of sex/gender differences (Grossi and Fine 2012).

Conclusion

Feminists have had much to say about neuroscience research, and feminist philosophy of science has drawn, in part, on issues arising from neuroscience in developing its particular approach. Starting from the insight that science cannot – and should not – be value-free, feminist philosophy of science has developed a number of ways to understand the influence of moral, political, and methodological values on the way science is conducted. This paper has argued that these tools can be very useful in understanding questions in neuroethics.

Abstract

Do men and women have distinct innate moral psychologies? Both Aristotle and Kant assumed so and viewed women as psychologically incapable of being fully moral. Conversely, John Stuart Mill and Carol Gilligan argued that women are equally as capable of morality as men, but also point out that women are nonetheless psychologically influenced by gendered roles and expectations. It is perhaps the most significant insight in feminist moral psychology that the distinction between the psychologies of oppressors and those they oppress is a much more significant psychological distinction to make and analyze than is the distinction of the moral psychologies of biologically sexed women and men. Moreover, the moral psychologies of oppressors and the oppressed are damaged in very specific ways. The psychologies of domestically abusive men are a case in point. Male abusiveness appears to be trait-like, with testosterone levels making only a minor contribution to the maintaining of this trait. The degree to

which a society is patriarchal and the role models to which men have been exposed play much larger roles in the development of the brains of abusive men.

Introduction

Neuroethics, as a field, is broad and not yet fully defined. There is, however, one clearly emerging branch of neuroethics devoted to the neuroscience of moral judgments and behaviors. The focus in this chapter is on a feminist approach to this particular branch of neuroethics. More specifically, this chapter examines the following: (1) if and to what degree there are sex and gender differences in moral judgments, behaviors, and traits and (2) if there are apparent differences, what are the most likely causes? The case is made that most differences are attributable not to sex-based brain differences between men and women, but to distinct and persistent types of psychologies found in oppressors and the oppressed.

It has long been assumed that women and men have different types of moral (and immoral) psychologies. Women have been assumed to be, in general, the more caring, nurturing, and empathetic sex; and men have been assumed, in general, to be the more rational, in-control, and duty-oriented sex. Conversely, women are stereotypically assumed to be the more manipulative, petty, and contriving sex; and men are stereotypically assumed to be the more violent, abusive, and aggressive sex. As a result of these widely held assumptions, there are sex-differentiated behavioral norms and virtues. Women are expected to cultivate such "feminine" virtues as compassion, emotional supportiveness, and kindness; and men are expected to cultivate such "male" virtues as strength-of-will, leadership, and courage. But are these supposed sex-differentiated moral psychologies and accompanying sex-differentiated virtues grounded on any brain-based, innate sex differences?

To answer this question, this chapter begins with a very brief history of gender-related psychological assumptions and norms found in the ethics of Aristotle (384–322 B.C.) and Kant (1724–1804). Both assumed that women are incapable of being fully moral and thus need the moral guidance of men. The chapter includes an even briefer history of feminist responses to the view that women are incapable of being fully moral, including the feminist responses of John Stuart Mill (1806–1873) and Carol Gilligan (1936–). Next there is a summary of perhaps the most significant development in feminist moral psychology: the insight that the distinction between the psychologies of oppressors and those they oppress is a much more significant psychological distinction to make and analyze than is the distinction between the moral psychologies of biologically sexed women and men. Moreover, the moral psychologies of oppressors and the oppressed are damaged in very specific ways. The chapter concludes with an analysis of the psychologies of abusive men to determine the degree to which male abusiveness is trait-like and the respective roles that testosterone and patriarchal societies play in the development of the brains of abusive men.

A Brief History of Gender and Ethics

Aristotle's virtue approach to ethics has been influential throughout Western history and remains influential in ethical theory today. Unfortunately, Aristotle's negative views on women have also been influential throughout much of Western history. Although Plato and a few other early male philosophers held more enlightened views on women, Aristotle's views were most influential on the views of Aquinas (1225–1274) and thus on the Catholic Church and Western society more broadly. Women, on Aristotle's view, are incomplete males who lack the ability to be fully rational and moral. In comparison to men, women are "more void of shame and self-respect, more false of speech, more deceptive, and of more retentive memory" (HA IX). In addition, unlike men, women are unable to exercise full control of reason over their appetites (NE, VII, 7–8; Pol, I, 13 (1259b 35–38)). Thus, according to Aristotle, it was morally necessary for women to be obedient to men, and it was impossible for women to engage in equal political or personal relationships with men. Aristotle viewed the marital relationship between a man and a woman as an unequal friendship in which the wife is expected to love the husband more than the husband loves the wife, and the wife is expected to recognize more honor and authority in her husband than he recognizes in her. Maryanne Cline Horowitz writes, "Aristotle's biological and psychological ideas about women parallel his political and ethical ideas about women. Together, these ideas are circular, self-supporting, and antifeminist to the core. On the one hand, woman's alleged inadequacies of body and mind backed up his general dictum that men naturally rule over women. On the other hand, Aristotle's unwillingness to view women as potential voting and ruling citizens and his unwillingness to recognize alternatives to the political and ethical hierarchy of husband over wife limited his viewpoint on female capacities" (Horowitz 1976, p. 212).

Kant's moral philosophy emphasizes the importance of rationality (detached from emotion and inclination) in moral deliberations. Like Aristotle and reflective of the societal norms of his times, Kant defended the views that husbands should be their wives' masters and that women should be denied citizenship. Also, like Aristotle, Kant viewed women as more likely than men to be swayed by emotions and passions and thus less likely than men to be motivated by rationality. Because of their psychological natures, women need the moral, legal, and political guidance of men. Unsurprisingly, he prescribed sex-differentiated virtues. Women were expected to emphasize the cultivation of the feminine virtues of charm, modesty, and subservience – virtues that benefitted men. Lawrence Blum, in a feminist analysis of both Kant's and Hegel's ethics, points out, in addition, that these philosophers' versions of moral rationalism are male-centered in two ways: "First, [moral rationalism] places at the center of its scheme of virtues qualities of character—rationality, strength of will, adherence to universal principle and duty—which can be seen . . . as 'male.' Correlatively it fails to provide a framework for expressing the significance of an important range of human virtues, which can be seen as 'female.' Such virtues are sympathy, compassion, human

concern, kindness, and emotional supportiveness. Second, it is a philosophy which reflects a male-dominated society, and implicitly sanctions male superiority" (Blum 1982, 294). For more on Kant's views on women and ethics, see Cash 2002.

Feminist Responses

John Stuart Mill was one of the first significant figures in the modern history of ethics to challenge the view that women were less capable of morality than men and to point out that both women's and men's moral psychologies are damaged by patriarchal societies. He writes that in order for women to be the obedient and "willing slaves" of men, men need to enslave women's minds by educating them to be subservient. He writes, "All women are brought up from the very earliest years in the belief that their ideal of character is the very opposite to that of men; not self-will, and government by self-control, but submission, and yielding to the control of others. All the moralities tell them that it is the duty of women, and all the current sentimentalities that it is their nature, to live for others; to make complete abnegation of themselves, and to have no life but in their affections" (Mill 1869, par. 25). When men rule in society, it is important that women's psychologies accept this and willingly accommodate a man-as-master and woman-as-slave arrangement of social life.

According to Mill, when men rule over women, it is not only women's moral psychologies that are damaged, but men's moral characters as well. He notes that "All the selfish propensities, the self-worship, the unjust self-preference, which exist among mankind, have their source and root in, and derive their principal nourishment from, the present constitution of the relation between men and women. Think what it is to a boy, to grow up to manhood in the belief that without any merit or any exertion of his own, though he may be the most frivolous and empty or the most ignorant and stolid of mankind, by the mere fact of being born a male he is by right the superior of all and every one of an entire half of the human race. . .What must be the effect on his character, of this lesson?" (Mill 1869, par. 33). Mill points out that it is impossible to know what men's and women's character traits would be if women were viewed as fully equal to men both in politics and in households, since no society has ever been set up that way.

Mill's views are a good historical lead-in to more recent developments in feminist ethics. Many of these recent developments grow out of the groundbreaking work of Carol Gilligan, a psychologist, who published *In a Different Voice: Psychological Theory and Women's Development* in 1982. Gilligan studied under and critiqued Lawrence Kohlberg (1927–1987), who proposed six main stages of moral development (see Kohlberg et al. 1983). Kohlberg's highest proposed stage was Kantian and involved making moral judgments by applying universal principles to moral situations. In developing his theory, Kohlberg studied young boys exclusively. When Gilligan expanded Kohlberg's project to include girls, it appeared that girls were, in general, less morally developed than boys, since they were more likely to focus on caring relationships than abstract justice when

reasoning morally, which would put them only at Stage Three on Kohlberg's scale of moral reasoning (Gilligan 1982). Gilligan later proposed that there are two incompatible moral perspectives – the justice perspective and the care perspective – neither of which is "higher" than the other on a moral scale and that both men and women are capable of shifting between these two perspectives (Gilligan 1987). Some feminist philosophers drew on Gilligan's work to propose ethical theories that emphasize and value the role of caring relationships, which are designated "the ethic of care." Other feminists objected that caring work is denigrated and undervalued in ethical theory because it has been tied to women and to other oppressed groups, and so eschewed the ethic of care, or at least urged caution that it not be gendered. The original hypothesis that women tended to be more caring than men was replaced with the hypothesis that members of oppressed groups, including women, are expected to do society's care work, which might make it more likely that they develop the necessary psychologies to do this. However, there is no evidence that women are naturally more caring than men, nor is it indisputable that women acquire traits associated with care if they engage in the caring work that is expected of them.

In 1990, Sandra Lee Bartky analyzed the influence of patriarchy on women's psychologies – picking up where Mill left off. In her book, *Femininity and Domination: Studies in the Phenomenology of Oppression*, she examines the ways that women internalize oppression. She writes, "I have been interested from the first in the nature of that 'femininity' that disempowers us even while it seduces us; I want to understand how the values of a system that oppresses us are able to take up residence inside our minds" (Bartky 1990, p. 2). She has taken up Mill's project using a wider range of theoretical tools, including linguistics, Marxism, empirical social science, and psychoanalysis. Unlike Mill, she also provides ways that women can resist the enslaving of their minds through feminist consciousness raising.

Clearly, what is provided above is an abbreviated and oversimplified history of gender and ethics. There have been many other developments and significant insights in both feminist ethics and feminist moral psychology (see, e.g., *Moral Psychology: Feminist Ethics and Social Theory* edited by Peggy DesAutels and Walker 2004). Nonetheless, it should be quite evident that from the very beginning (Aristotle), ethics has been developed with the assumptions that men should rule women and women should be obedient and pliable. Norms of femininity even today expect women to be first and foremost attractive to men and supportive of men. Conversely, norms of masculinity require that men contain their emotions, refrain from caring sentimentality, and stay in control of themselves and those around them.

The Brains of Oppressors and the Oppressed

The psychologies of women and men develop within and are influenced by patriarchal social norms and structures. Allen Johnson summarizes the key features of a patriarchal society: "A society is patriarchal to the degree that it promotes male

privilege by being *male dominated*, *male identified*, and *male centered*. It is also organized around an obsession with control and involves as one of its key aspects the oppression of women" (Johnson 2005, p. 5). Contemporary societies, including such "developed" societies as that found in the United States today, remain patriarchies. Thus, even today and throughout the world, women's psychologies are, at least to some degree, the psychologies of the oppressed, and men's psychologies are, at least to some degree, the psychologies of oppressors. If this is the case, where does neuroscience come in? So far, many of the neuroscientific insights on moral cognition have come from fMRI studies while subjects think through moral dilemmas and make moral judgments. Of course it is impossible to conduct fMRI studies on subjects as they go about their daily lives and engage in moral and immoral behaviors. And it is also impossible to conduct fMRI studies on the cognitive processes involved in internalizing norms of femininity and masculinity. In other words, neuroscientists are going to find great difficulties in examining and understanding the brains of oppressors and the oppressed. And even if this becomes more possible through better experimental designs, there will remain the difficulty of separating nature from nurture in the development of sex-differentiated behaviors and character traits.

Most feminists would agree that the brains of women and men are biologically sexed to at least some minimal degree, but they would emphasize in addition that men's and women's brains are embedded in particular social structures with learned patterns of behavior that contribute to how these brains are organized and shaped. Perhaps the most obvious biological sex difference with the potential to differentially affect men's and women's brains is the level and types of hormones that affect brain development and organization. There is no denying that starting in the womb, males and females have differing hormones and differing hormone levels. And there is no denying that hormones play a role in brain development, organization, and functioning. But it remains unclear exactly what the cognitive effects of these hormonal differences really are. For example, Rebecca Jordan-Young's recent book, *Brain Storm: The Flaws in the Science of Sex Differences* (2010), convincingly shows that hormone-based "brain organization theory" is not as scientifically grounded as both neuroscientists and the popular media would lead us to believe. Nonetheless, some progress is being made in determining the respective roles that hormones, situational factors, and cultural norms and practices play in shaping cognition and behavior. As a result, perhaps we can make progress in answering the following sorts of questions: Do differences in men's and women's hormone levels affect their moral judgments and behaviors? Do differing levels and types of hormones absolve men and women in differing ways and degrees, of moral responsibility for their actions? What role does testosterone play in aggression and thus in the committing of violent crimes? Are more men than women in prison because their "moral brains" differ in fundamental ways?

Recently, a number of ethicists have rejected abstract and ideal theorizing in favor of more empirically informed approaches to explaining and prescribing moral cognition and behavior. Of special interest to some of them (e.g., John Doris and

Gilbert Harmann) is the degree to which personality traits or dispositions are the determinants of at least some moral behavior. Doris, for example, appeals to a number of psychological studies including the Good Samaritan experiments, the Milgram experiments, and Holocaust research, to argue that situations are much more powerful determinants of behavioral regularities than are supposed character traits (Doris 2002, p. 26). Doris focuses primarily on the ways that situations override supposed virtuous traits and seldom discusses vicious traits. Although Doris is right to say that situations play a significant role in determining moral behavior, there is also good reason to argue (contra Doris) that certain vicious patterns of behavior are tied to vicious character traits for two main reasons: (1) vicious behavior is often perceived by the vicious agent to be in that agent's best interest, and thus the agent benefits from, values, and consciously perpetuates certain vicious traits, and (2) in the case of male domestic abusers, a persistent and pervasive situation (i.e., patriarchal culture) combined with certain personal histories (i.e., exposure to abusive behaviors when growing up) combine to produce the rigorous vicious character trait of abusiveness to women that is predictive of patterns of vicious abusive behaviors. Psychological studies of male domestic abusers show that a belief in male entitlement combined with early exposures to males dominating and abusing women contributes to and perpetuates vicious character traits in certain men that result in their exhibiting regular patterns of abusive behaviors in domestic settings.

The Psychologies and Traits of Male Domestic Abusers

It is helpful at this point to provide some statistics for the United States published by the US Department of Justice:

- The number of victims of intimate partner crimes in the United States was approximately 907,000 in 2010.
- From 1994 to 2010, about four in five victims of intimate partner violence were female.
- Most female victims of intimate partner violence were previously victimized by the same offender, including 77 % of females ages 18–24, 76 % of females ages 25–34, and 81 % of females ages 35–49 (Catalano 2012).

As these statistics show, violent domestic abusers are almost exclusively male, their victims are almost exclusively female, and abusers tend to be repeat offenders. Why is that? And just how likely is it that a particular domestic abuser will continue to abuse or even escalate the abuse of his domestic partners? Knowing the answers to these questions could be lifesaving information both for the surviving victims of abuse and for the new partners of past abusers. In other words, it could be lifesaving to know whether or not men with a history of domestically abusive behavior have an abusive vicious character trait and as a result can be expected to continue to abuse their domestic partners. Thus, the answer to Doris's more general question about the degree to which behavioral regularities can be attributed to character traits

becomes potentially an answer with life-and-death consequences in the case of violent abusive behavior. Too often, women think that abusers can and will change with changed circumstances.

To address the degree to which abusive behaviors in domestic settings are tied to abusive character traits, and could be viewed as a type of Aristotelian vice, it is worth starting with Aristotle's discussions of virtues and vices. Although Aristotle's views on women are both unfounded and morally problematic, his virtue approach to ethics grounds and is relevant to contemporary discussions of virtues and vices. It is also worth looking at the latest research on brain-based causes of violent and aggressive behaviors and on the psychologies of heterosexual male abusers. The most likely conclusion is that in most cases, those men who are domestically abusive do have trait-like tendencies to be abusive and thus that they have vicious characters in an Aristotelian sense. However, these abusive character traits are not tied primarily to male androgens. Rather, they are formed within patriarchal social structures and maintained in individual males primarily by habituation.

For Aristotle, both vicious and virtuous character traits are acquired through habits often from our youth. In *Nicomachean Ethics*, Aristotle states, "A state [of character] arises from [the repetition of] similar activities. . .. It is not unimportant, then, to acquire one sort of habit or another, right from our youth; rather, it is very important, indeed all-important" (Aristotle NE, 1103b23–25). To develop a particular virtuous character trait, the goal is to find the mean between the excess and deficiency tied to the correlative vices associated with that trait. Aristotle might argue that domestically abusive men (hereafter referred to as male abusers) are vicious because they fail to find the mean tied to anger, mildness. They suffer from some combination of the excesses of anger he refers to as "irascibility," "bitterness," and "irritability." He states, "The person who is angry at the right things and towards the right people, and also in the right way, at the right time and for the right length of time, is praised" (Aristotle NE, 1125b32–33). Aristotle elaborates on the different types of people who have excess anger, "Irascible people get angry quickly, towards the wrong people, at the wrong times and more than is right; but they stop soon, and this is their best feature" (Aristotle NE, 1126a13–17). But, he notes, "Bitter people, however, are hard to reconcile, and stay angry for a long time, since they contain their emotion. It stops, however, when they pay back the offence; for the exaction of the penalty produces pleasure in place of pain, and so puts a stop to the anger. . .. This sort of person is most troublesome to himself and his closest friends. . .. The people we call irritable are those who are irritated by the wrong things, more severely and for longer than is right and are not reconciled until [the offender has suffered] a penalty and corrective treatment" (Aristotle NE, 1126a20–28). As can be seen later in this chapter, many male abusers probably best fit the "bitter" category although their vice is compounded by a tendency to exhibit controlling and dominating behaviors towards their domestic partners as well as expressions of contempt. Even though Aristotle makes it clear that men should rule women, he would not agree that men should rule women abusively, and he advocates for their having a type of friendship. He thinks that men and women's

roles in the household should be harmonious and bring pleasure to all. He notes, "Human beings. . .share a household not only for child-bearing, but also for the benefits in their life. For from the start their functions are divided, with different ones for the man and the woman; hence each supplies the other's needs by contributing a special function to the common good. Hence their friendship seems to include both utility and pleasure" (Aristotle NE, 1162a21–24). When Aristotle's view that men should rule women is updated to the view that domestic partners should have equal status, there is much that can be learned from Aristotle's extended discussion of friendship. Certainly, abusive men are not virtuous friends of their wives, girlfriends, or lovers, and Aristotle would most likely judge abusive men to have vicious character traits.

Building on Aristotle's views on virtue and character traits, it is now possible to turn to more contemporary discussions of a virtue approach to ethics. In particular, it is relevant to turn to some of Doris's views found in his book, *Lack of Character: Personality & Moral Behavior* (2002). According to Doris, "virtues are supposed to be *robust* traits; if a person has a robust trait, they can be confidently expected to display trait-relevant behavior across a wide variety of trait-relevant situations, even where some or all of these situations are not optimally conducive to such behavior" (Doris 2002, p. 18). So, by Doris's account, in order for male abusers to have vicious character traits, it is necessary to determine if male abusers "display trait-relevant behavior across a wide variety of trait-relevant situations." This could be a tricky determination. One feature of most male abusers is that this abusive trait only shows up in domestic settings. Work colleagues and extended family members often have no clue that their colleague or relative is abusive, since this behavior is not exhibited outside of the home. So, in one sense, male abusiveness is not a global trait. On the other hand, it is not, as Doris would put it, an "extremely grained" merely "temporally stable" local trait. Abusiveness does consistently and persistently occur in "trait-relevant situations." It appears that the trait-relevant situation for a domestic abuser just is the situation of being in the privacy of his own home in the company of his female partner. A significant portion of his life takes place in this situation. If a man exhibits persistent patterns of abuse with a female partner over time, or if the abuser changes his female partner, and the abuse continues with the new partner, this counts as being robust (in the sense of constancy) in "trait-relevant situations," and he should therefore be seen to have the vicious character trait of being a domestic abuser. This trait also has what Doris terms, "an evaluative dimension," when the male abuser values being abusive. It is shown in what follows that he does indeed value being abusive because abusiveness as a trait is in his self-interest to maintain. Doris believes that almost all behavioral regularities are explained by situational regularities (Doris 2002, p. 26). The perspective taken in this chapter, on the other hand, is one in which male abusiveness is viewed as a "robust dispositional structure" developed from youth, maintained by habit, valued for its self-interested ends, and predictive of future patterns of behavior regardless of the specific domestic situations in which or the specific female partners with which male abusers find themselves.

Neuroscience and Male Abusers

What do contemporary psychologists and neuroscientists have to say about male abusers? Do domestic abusers merely exhibit what Aristotle terms "an excess of anger"? If so, would "anger management" classes best address and treat their abusiveness? Are there other aspects to their psychologies that contribute to their being abusive? Why are abusers almost exclusively male and their victims almost exclusively female? The answers to these and related questions are difficult to tease out of the psychological and neuroscientific literature. The answer to why abusers tend to be male might lie in a closer look at male versus female brains. Perhaps circulating levels of testosterone (really androgens more generally) causally correlate with levels of aggression, or early exposure to testosterone explains how boys' brains become permanently wired for more aggression than girls' brains do. And perhaps high levels of aggression causally correlate with high levels of abusiveness. Then, instead of curtailing the expression of felt aggression in some way, all we would need to do to prevent domestic abuse is lower the testosterone of abusers (or raise their levels of estrogen).

Unfortunately (or fortunately?), this simple causal picture falls apart rather quickly. For one thing, male abusers tend not to be overly aggressive or angry in nondomestic settings. This would mean it is not a simple brain chemistry problem, since if it were, the aggressive and angry behaviors would show up more globally. For another thing, even if abusiveness were tied to being overly aggressive, neuroscientists and psychologists have multiple and often-conflicting measurements for aggression and publish often-conflicting studies on the relationship between high levels of aggression and high levels of testosterone. In their article on testosterone and social behavior, Booth et al. (2006) summarize the findings as follows:

> "Testosterone poisoning," now part of the language is a popular explanation for excessive "manly" behaviors such as boasting, violence and pugnaciousness. . .. In fact, there is little empirical support for these popular assertions. We cannot say that they are all false because research literature is not conclusive. But it is already clear that there is no simple one-to-one relationship between testosterone and machismo or aggressiveness or sexuality. It seems wiser to view testosterone as one component in a confluence of interacting physiological, psychological and social influences that affect behavior. (Booth et al. 2006, p. 167)

In further addressing the role that social influences play, they state:

> We do not assume that testosterone is a mechanism in and of itself that causes or creates behavior. Instead, we assume that testosterone increases the likelihood that certain behaviors will be expressed, if the propensity for that behavior already exists, and the expression of that behavior is consistent with social contextual demands. Characteristics of the social landscape permit, stimulate, suppress or set the stage for the expression of specific testosterone-behavior relationships. (Booth et al. 2006, p. 170)

For a more detailed and up-to-date analysis of the role that testosterone does and does not play in male aggression more generally, see Jordan-Young (2010).

So, based on this and a number of other related articles, it appears that testosterone is one factor among many in a complex confluence of factors (both brain based and culturally based) that underlie behavior. Most significantly, testosterone

levels alone do not directly cause or create behaviors. One way to think of the causal role of hormones in behaviors is that both men and women are in “hormonal situations” as well as social situations and that hormonal situations can and do influence patterns of behavior to at least some if not a very limited extent. It is worth extending Doris’s view of situations to include brain chemicals as one of many confluent causal factors affecting an agent’s cognition and behaviors. These chemicals would include not just hormones but any naturally occurring neurochemicals that affect mood, cognition, and behavior such as oxytocin, dopamine, and endogenous opiates. For more on the variety of neurobiological contributors to social and moral behaviors, see Suhler and Churchland (2011).

Male Abusers and Entitled Control

If an abuser’s “testosterone situation” is only of slight to no relevance to his abusiveness, what causes and maintains male abusive traits? Can male abusers be changed? There are a number of books and articles in the psychology literature attempting to answer these questions often with the motivation of providing psychologically accurate explanations for and guidance to abused women. Lundy Bancroft’s book, *Why Does He Do That? Inside the Minds of Angry and Controlling Men* (2002), is especially insightful. Bancroft has worked as a “counselor, evaluator, and investigator” for over 2,000 cases of what he terms “angry and controlling men” (Bancroft 2002, p. xvii). Although there is a range of patterns of abusive behavior and types of abusers, male abusers have much in common. Bancroft and others who analyze abusive behavior stress that abusers are mostly focused on control. Here’s Bancroft’s summary of the general pattern of behavior found in almost all abusers:

> Periods of relative calm are followed by a few days or weeks in which the abuser becomes increasingly irritable. As his tension builds, it takes less and less to set him off on a tirade of insults. His excuses for not carrying his weight mount up, and his criticism and displeasure seem constant. . .. One day he finally hits his limit, often over the most trivial issue, and he bursts out with screaming, disgusting and hurtful put-downs, or frightening aggression. If he is a violent abuser, he turns himself loose to knock over chairs, hurl objects, punch holes in walls, or assault his partner directly, leaving her scared to death. After he has purged himself, he typically acts ashamed or regretful about his cruelty or violence, at least in the early years of a relationship. . .. You then begin to see the signs of his next slow slide back into abuse, and your anxiety and confusion rise again.. . .. The abusive man tends to mentally collect resentments toward you until he feels that you deserve a punishment. After he blows, the abuser absolves himself of guilt by thinking of himself as having lost control, the victim of his partner’s provocations or his own intolerable pain. . .. “There is only so much a man can take.” (Bancroft 2002, pp. 147–148)

Notice how much of this description fits with Aristotle’s description of a bitter man: “Bitter people, however, are hard to reconcile, and stay angry for a long time, since they contain their emotion. The anger stops, however, when they pay back the offence; for the exaction of the penalty produces pleasure in place of pain, and so puts a stop to the anger. . .. This sort of person is most troublesome to himself and

his closest friends" (Aristotle, NE, 1126a20–27). "Troublesome" is one way to put it. "Terrifying and life-threatening" is another. Notice, too, that Aristotle does not connect this behavior with abusive or controlling behavior. Contemporary discussions of abusive men stress their need to dominate and control women.

Bancroft disabuses his reader of a number of myths about such men. One of these myths is that they have violent, explosive personalities. He points out that most abusive men are perfectly calm and rational in nondomestic settings (Bancroft 2002, p. 32). He also points out that abusers do not lose control; rather they consciously give themselves permission to embark on abusive rampages, both physical and verbal. For example, when police show up at the door, they are perfectly capable of immediately reverting to "in-control" behavior and then picking up where they left off once the police leave. Bancroft stresses, "an abuser almost never does anything that he himself considers morally unacceptable. He may hide what he does because he thinks other people would disagree with it, but he feels justified inside.... In short, *an abuser's core problem is that he has a distorted sense of right and wrong*.... the abuser's problem lies above all in his belief that controlling or abusing his female partner is *justifiable*" (Bancroft 2002, pp. 33–35). It could be added that the belief that men are justified in abusing women is closely related to gender role stereotypes that are promulgated in society, including that a man should be the king of his castle with entitled control over those who live in his castle. For a less clinical and more scholarly discussion of male abusers as coercive controllers of women, see Evan Stark's *Coercive Control: How Men Entrap Women in Personal Life* (2009).

One reason abusiveness is trait-like in its persistence is because abusers benefit in a number of ways from being abusive. As Bancroft points out, they become attached to privileges and benefits that come from getting their way, controlling their partners and making their own needs top priority. It is extremely difficult to treat male abusers. Bancroft asserts, "*...If we want abusers to change, we will have to require them to give up the luxury of exploitation*" (Bancroft 2002, pp. 151–157). He also points out that, "they have habits of mind that make it difficult for them to imagine being in a respectful and equal relationship with a woman" (Bancroft 2002, pp. xx–xxi). From their perspectives, they *deserve* to rule, to apply different standards of behavior to themselves than they do to women, and to treat women with contempt. This perspective is learned from and reinforced by abusive fathers or stepfathers and from a patriarchal society more generally. One of Aristotle's main points is that a man's ability to become virtuous depends on his having good role models.

Conclusion

In conclusion, it appears that the majority of male abusers have robust abusive traits with no incentive to modify these traits and much to gain by maintaining these traits. Testosterone may be a minor contributor, but it is not the main culprit. Rather, most abusers develop ingrained habits of abuse at an early age modeling their attitudes and behaviors on those of close family members. In addition, these abusive traits are developed and maintained in an all-pervasive situation – that of a patriarchal culture

in which physically stronger men have power and rule over women in the media, pornography, politics, and religion. More generally, it would seem that vicious behaviors that significantly advantage agents are more likely to become robust traits than are virtuous behaviors. Clearly, abusive vicious traits advantage those in power and help to maintain that power over those who are subject to this power.

Situationists (i.e., those who attribute behavior more to situations than to supposed character traits) such as Doris have much less of a case than they think they do. They, like most virtue theorists, have been looking at the wrong kinds of traits. It is relatively easy to find situations that make a "good" person behave badly. It is much more difficult to find situations that make a powerful "bad" person behave well. Traditionally, virtue theorists have focused on the virtues, but as Robin Dillon points out, virtue ethicists including situationists need to develop theories on *both* virtues and vices. Dillon writes, "We need to understand not only what kinds of persons to be but also what kinds not to be, not only what traits foster resistance to oppression and emancipation but also what traits support domination and thwart emancipation, and what cost to character struggles for liberation and struggles to maintain domination might exact" (Dillon 2012, p. 83). It could simply be added that when abusive and controlling traits show up in members of oppressive groups (e.g., particular men in patriarchal societies), they are likely to be more persistent and thoroughly trait-like than are their virtues.

This chapter ends with a proposed agenda for those wishing to further pursue a feminist approach to the neuroscience of ethics. Future efforts could be directed towards the following: (1) critically examining ways that neuroscientific research on moral psychologies is embedded within and contributes to gender-based social biases and injustices, including oppressive norms tied to "feminine" and "masculine" brains, and (2) developing theories of "moral brains" that are informed both by neuroscientific findings (including findings of sex-based differences) and by ethical theories (including feminist theories). Socially and culturally attuned feminist neuroscience will help to ameliorate tendencies to oversimplify the causal roles of biology (e.g., hormones) in sex-differentiated patterns of behavior. This chapter provides just one example of how it is possible to use a feminist approach to analyze sex-based differences in moral psychologies and behaviors, but there are many other examples worth analyzing.

A Curious Coincidence: Critical Race Theory and Cognitive Neuroscience

90

Anne J. Jacobson and William Langley

Contents

Abstract

In this chapter, we will consider questions about implicit bias. A case of implicit bias typically involves an agent's action being in conflict with some sincerely professed values and beliefs. Thus, Jones maintains non-Christians may be as honest as Christians, but in practice, Christians are accorded more credibility. Later we will add more features in order to characterize the phenomenon more precisely, but we now have enough to start with.

Implicit bias raises questions in several areas. In **moral theory**, one of the most crucial issues concerns responsibility and guilt. In **psychological studies**, the question of how to substantially moderate or eliminate implicit bias is very important. Critical race theory can employ notions of social groups to bring these two areas together. On the one hand, critical race theory can direct our attention

away from the facts of individual agency, as opposed to social engagement. From this perspective, culpable wrong-doing comes from complicity in continuing inequalities. A solution is to break down the isolations obtaining among members of different groups.

Recent work from Read Montague's labs can be seen as giving us a neurological model of how implicit bias operates. Further, they have found that expertise protects one against it. We will explore the similarity between the critical race theory's breaking down isolation and the acquisition of expertise some neuroscientists have stressed.

Unfortunately, these similarities do not appear to give us a powerful way to eliminate implicit bias. I conclude by pointing out how these considerations may nonetheless provide a more effective use of some other techniques.

Introduction

This chapter will look at the topic of implicit bias from three perspectives: critical race theory, cognitive neuroscience, and moral theory. In contrast to the standard analytic approach, critical race theory and cognitive neuroscience can be seen to share a view about how to approach implicit bias on matters such as race, gender, disability, sexual orientation, and so on. The approach has some important differences from what we can see as standard philosophy, and those areas of psychology that are congenial to it. For example, it is not wholly individualistic; that is, it does not focus on the individual as the only target for change. Relatedly, it is usually employed with groups of people. Intuitively speaking, using groups can bring in several benefits, among them an increased chance of stability as members reinforce each other's practices. (Examining the effectiveness of forming particular kinds of intentions we will regard as an individualistic approach (Sheeran and Orbell 1999); having people share stores with people of other races is not.) The news is not, however, all good. There remain very serious questions about whether we have discovered a strategy for the sort of change in a society that a significant decrease or elimination of bigotry involves. As we will see at the end of the chapter, the approach can hardly be a complete strategy if our goal is the creation of a more just society.

What Is Implicit Bias?

A paradigm case of implicit attitudes often cited concerns schemas, which we can think of as ways of organizing, and anticipating experience. Our schema for dogs, for example, may include barking and being loyal. We can think of schemas as closely related to stereotypes. Schemas, we can say, are ways of organizing some experiences and stereotypes are the result of using schemas.

For many readers, schemas and stereotypes label familiar phenomenon. A high proportion of philosophers have read Hume on causation and constant conjunctions. In the Anglophone tradition, it may be that almost all of us have. One of Hume's

most basic ideas is that observing type-A things or properties conjoined with type-B leads human beings to feel there is a connection between two such items; in addition, we will expect a B when we observe an A. To take an example related to our discussion, if in one's experience, everyone in a leadership position is male, then one comes to feel there is a connection between the two and to expect a male when one is about to meet a leader (Valian 1999).

I have used the word "feel" in explaining Hume's thought, because it is important that our sense of a connection and our expectations are not the product of reason. They are much more instinctual, for nature, who made us, knows that reason is not a reliable source of these important features of our thought. And making the connections is very important and, for Hume, forms the core of our knowledge.

A great deal of recent cognitive psychology and cognitive neuroscience bears this view out (Montague et al. 1994; McClure et al. 2004). We will in fact make use of one such case, developed by Ann Harvey (Harvey et al. 2010; Kirk et al. 2011). Her work addresses the questions we will shortly raise.

Our treatment of these two topics is not going to come to any easy answer. We will instead accomplish two things. First, we will bring together areas of discourse that still largely exist apart. Secondly, we know that shaming and blaming the perpetrators of bias can very easily backfire; very standard advice is to avoid blaming. At the same time, the prospect of shame and blame can have very dramatic effects on behavior. As we start to turn to non-individualistic pictures, we may well find ways in which shaming and blaming can be employed without their familiar toxic effects.

Bias in Action

One consequence of instinct's role is that it is quite hard not to form the expectations. They are cognitive correlates to bodily instincts, such as blinking when something is in an eye. But, while they are instinctual, they may have profound social impact. Suppose all the professors one has observed are male; the chances that one will select a female to fill a vacancy in the department are slim. One will feel there is a connection between being a professor and being male.

We will focus on biased actions and attitudes that are actually or potentially harmful to the targets of the bias. The biases we will look at are unjust. It is possible to be biased against members of a class for quite good reasons, and actions coming from such a bias may not be unjust; thus, one might be biased against a group's judgments on abortion. Further, we will take attitudes and actions to constitute the bigotry we are interested in when they are accompanied by power differentials. Thus, a white man refusing to hire people of color may be being racist, because in our society, whites have more social power than people of color. In contrast, an average 10-year-old child who does not want to play jump-rope with any adult is not demonstrating ageism, as we will be using standard terms for bigotry.

These scenarios based on stereotypes may play out even when I am unaware of the connection I have made. Thus, despite my conscious view that gender and

intelligence are not connected, I might still, unbeknown to myself, let such associations influence my action.

There is a general assumption in the literature on implicit bias that discoveries in one area of bias (e.g., race or gender orientation) should transfer to the other. Some of the work I will discuss has to do with race, and another large part has to do with one sort of implicit bias money can create. This might seem quite unsatisfactory if the field was more developed, but we are still at a very early stage, when similarities in quite different areas are very much worth investigating.

Our discussion is somewhat focused on racial bias, but it is motivated by a deep concern also for gender bias, and particularly how it plays out in the somewhat unregulated context of academia. In 2005, a report sponsored by the American Historical Association (http://www.historians.org/perspectives/issues/2005/0501/0501new2.cfm) wrote:

> There is more than enough resignation, bitterness, disillusionment, and discouragement to warrant a more serious and extensive consideration of gender in the profession than we were able to carry out in this survey. . . . The profession as a whole should be concerned that so many successful women feel they have suffered from gender discrimination. Female talent is being squandered in fights over large and small issues that could be ameliorated by the attentiveness of administrators, department chairs, and colleagues, and the establishment of more transparent institutional procedures.

It may well be a mistake to take this harassment of women in academia as like that faced by African-Americans, but it can certainly be severe. What can we do about the many people who, because of bias in their society, have their talent squandered?

Responsibility

Bigotry appears to be an attitude of individuals. If we want to consider how to combat it, we need to look the conditions under which individuals are held responsible, when they are. It seems obvious that such a perspective would tell us something about causes, even if less than the whole story. We need to advance a warning, however, which we will return to at the end of this chapter. One remarkable fact about actions prompted by implicit biases is that they are often not the objects of disapproval or blame. Many of them are the result of decisions that do not wear the bigotry on their sleeves. But there is another common reason: Blaming and shaming generally do not work to diminish prejudice and prejudiced actions. People become very defensive and refuse to consider the critic’s point of view. Blaming is not, then, generally cited as one of the weapons we have when fighting bigotry.

Let us now turn to actions. Simplifying somewhat, we can say that the standard philosophical theorists hold a linear causal view of action of a fairly Davidsonian kind; this model may appear even in extended, embodied approaches (Cash 2010). That is, actions are seen as the endpoint of a causal progression from motive to act. One wants a chocolate; one picks a piece up and puts it in one’s mouth. But with implicit prejudice, a serious problem arises immediately. Implicit prejudice

arguably involves ignorance of what one is doing; supposing the chocolate is actually meant to be a present for one's host, ignorance may mean one does not know one is eating some of the host's present. A condition of responsibility is knowledge of what one is doing, and so ignorance may reduce or eliminate responsibility, on the standard philosophical view (though not for all theorists (Holroyd 2012)).

If we consider the question of responsibility abstractly, then it may not seem odd to count bigots as absolved from blame if they are genuinely ignorant of their motives. However, it is difficult to accord innocence to jurors who sentence people to death, because their implicit prejudice leads them to think that people of some ethnicities are not honest. As one would expect, then, critical race theorists are much less enamored of a dismissal of questions of wrong-doing. Their view comes with a different or additional view of action and responsibility. This different view emerges from a number of considerations, one of which will we be considering below.

As we look at models of blameworthy actions, our perspective will change. This should lead us, among other things, to be careful about how we describe what we are doing. A focus on the possession of attitudes by individuals narrows our attention considerably. There are many, many ways in which the more structural factors of a culture may in effect carry bias with them and so induce or re-induce biases. If we are interested in solving a political problem of any magnitude, then we have to include such structures in our targets. In addition, it may be that ameliorating the attitude problem will lessen the chances of effective group political action to solve the structural problems. In light of such concerns, we should look at this chapter so far as directed toward a psychological question, rather than providing a political solution. The psychological question is about how to change attitudes, and not about how more generally to create a more just society.

The Debate About Moral Responsibility

While critical race theorists are not about to excuse whites for judging people of color much more harshly than whites, analytic philosophers have a less easy time saying that the whites are morally responsible. One important obstacle to saying they are morally responsible is, as we have seen, that we tend to think that ignorance provides a very good, firm excuse. If one honestly thinks Mary is a less good student than Joe is, how can one be morally responsible for giving her grades lower than those she merits; that is, ones that are comparable to Joe's?

There are three different, but fairly standard responses from analytic philosophy to the blameworthiness of one's action. All three appear to operate with a similar structure for actions we have looked at. We will start with what we might consider to be a barebones approach that employs a simplified Davidsonian theory, but one that can still be considered the standard theory (Schlosser 2011). This approach understands actions as points in a causal process, ones that start with internal events such as beliefs and desires. Thus, I might desire a piece of chocolate and, checking my purse, find some Hersey kisses that I assume I picked up leaving a restaurant. If it turns out that

they are not mine, that someone else stuck them in my bag by mistake, my mistake about the true origin vitiates any charge of misusing someone else's possession.

A second view, one that makes agency even more demanding, adds in that the action must stem from a self with some unity, and particularly with some unity of one's values. Unconscious elements cannot be part of this unity, and so in a real sense, the action is not one's own action. As a consequence, one is not morally responsible for it (Arpaly and Schroeder 1999; Frankfurt 1971, 2008; Norris 2010).

We can understand the first and second views as potentially excluding responsibility. However, ignorance comes in degrees. Perhaps a friend asked if she could store some candy in my purse; my simply forgetting her request may not be an effective excuse. A third approach may, then, view the matter more as allowing that our judgments of awareness and responsibility may vary from one case to another (Holroyd 2012).

All of these reactions allow the possibility that a sexist grader or a racist juror may be entirely innocent in their unjust grading or sentencing. Nonetheless, we may start to feel our views at odds with this outcome if we look at another case of implicit bias. It turns out that pharmaceutical companies often enough turn up at doctors' offices with free and rather good lunches. This is not done to make sure the medical profession is well nourished. Rather, it has a payoff for the companies, which is that the doctors are considerably more likely to prescribe the medicine the representatives want to promote. At the same time, doctors typically do not think that the lunches bias them in any way. But doctors have a duty to prescribe medicine on more medically relevant grounds than the quality of free lunches they receive. If the lunch has a strong effect on their actions, it is on the cards that there is a failure to fulfill their duty. And typically, we do not think ignorance generally simply excuses such failures.

We can extend the claim. We have a duty, we might say, to form accurate beliefs about other human beings if such beliefs are to affect deeply the distribution of goods in our society and more generally the just treatment members receive. Just as we should query whether we are prescribing the best medicine to patients or giving our students accurate grades, so we have some obligation to query our tendency to think people of our race are more honest and less likely to be criminals. (A somewhat related point occurs in (Shotwell 2011). We might think of ourselves as having a covert checklist, with of the moral quality of an action dependent on how they should be completed.

The checklist fits nicely into the causal model of actions, where, we can see, the guilt accompanying such an action, if there is any, depends on the actions and its antecedents. Nonetheless, there are less obvious and more unattractive effects of such an approach that we need to look at. For one thing, the focus is very limited: Typically, we look just at a person, an action, and an effect, all abstracted from the social context. In addition, the examples foreground the white person as agent, and the minority person is seen as passive recipient. Consequently, they recapitulate one of the central tropes of discrimination.

Critical race theory is more powerful when it takes such a picture as not the only picture of moral quality and, moreover, as positively misguided in some fundamental ways. A key notion for critical race theorists is complicity, as opposed to guilt and

responsibility. Guilt and responsibility are seen in terms of the linear causal model. However, that leaves out the important feature of complicity. Simply being a member of an unjust organization or society strengthens such groups, and makes us complicit in what they are able to accomplish, even when we do not perform directly harmful or prejudicial actions. Looking at the complicity involved in continued membership in an unjust group brings our attention to the group, its problems, and those who suffer or benefit from it. The discrimination people of color suffer is no longer simply a matter of a white person's moral problem (Applebaum 2010).

Along with the notion of complicity go ideas about how to address it. What is common to critical race theory and the cognitive neuroscience we have seen is a set of ideas that I will call a group-based acquisition of expertise. One obvious form of this is the mixed classroom, where white students explore with students of color both the advantages of being white and the disadvantages attaching to a minority position. Such classes are not, however, simply engaged in intellectual enterprises. They are also like encounter or consciousness raising groups, as participants seek a deeper understanding of their biased social setting.

Such training should reflect not just the many dimensions of bigotry and its harms, but also different modes of access to the presence of such bigotry and the potential for its presence. A person with such expertise should be able to do more than correctly label completed actions. They should also usually be able to recognize situations, at least in their normal cultural setting, that are likely to yield discriminatory attitudes or actions, and body language that heralds its display. The expertise we are describing is like those found in a number of other fields. Thus we would expect an expert in twentieth century US art to be able to list various periods in Warhol's work and to recognize them when shown samples.

The comparison between expertise in prejudice and expertise in art is not random. We are about to turn to a neuroscientific investigation of biased judgments about art and how expertise affects the acquisition of such bias.

The Art-Viewing Paradigm, Part One

In the experiment, subjects are asked to judge the quality of paintings they are shown. The paintings are created for the experiment, and not ones the subjects have seen before. Their judgments reveal very marked biases in the subjects, which are due to the context. The pictures are viewed on paper that has a company's logo on it. Though they all get the same amount in the end, the subjects are told that there is a considerable difference between the companies in the amount they are contributing. One company may be sponsoring participants at $300 each, while another only contributes $50 each. Subjects are told that the logos are just randomly assigned, and their size and placement makes no difference.

The subjects overwhelmingly pick the pictures on which the logo of the more generous company appears. Further, there is no awareness on the part of the subjects that their judgments are affected by the differences in contributions. They say things like, "I guess I just have the same judgment as that company had."

Subjects' preferences showed up both in neural activity and in reported preference. When viewing paintings paired with the sponsor's logo, investigators noted increased activity in the ventromedial prefrontal cortex (VMPFC), an area of the brain believed to encode differences in preference. Similar activity was observed in a 2008 experiment in which the effect of price on wine taste preference was tested (Plassmann et al. 2008). Test subjects showed a consistent preference for the "sponsored" paintings in the follow-up behavioral response questionnaire. Researchers also tested for the effect in cases where companies made a "mere offer" of sponsorship. In cases where only one of the two companies offered to sponsor the experiment but neither was selected, subjects still showed a significant preference for paintings paired with the offering company's logo.

The team designing and executing the experiment think the result is due to a fairly deep need on the part of human beings to reciprocate when they receive gifts or benefits. The subjects are in effect giving back to the more generous company. They are not, however, aware of what they are reciprocating.

We have in this case some of the most important features of racial bias, and particularly implicit bias. First, there are the discriminatory judgments. Secondly, we have a hypothesized mechanism. Reciprocity is the problem in the art-viewing case. And while we do not know what the mechanism is for racial bias, it is reasonable to look for some mechanism that has some of the same features reciprocity has, such as being a deep-seated and a widely spread trait. Finally, and most importantly, the subjects are not aware of what is driving their judgments.

The Art-Viewing Paradigm, Part Two

There are all sorts of occasions in which a gift might be given in order to receive a more favorable outcome on some topic. Pharmaceutical companies notoriously are great gift givers. Doctors typically say that a company's free lunches do not affect what they prescribe, but the companies clearly regard it as a strategy worth investing in. Work with the art-viewing paradigm backs the companies' judgment.

If we want to think about the moderation or elimination of bias, the next experiment from the same group gives us a lot of information. The researchers brought together a group of art experts and subjected them to the picture-viewing paradigm, including the information about who was paying what. In the outcome, there was no sign of bias. Expertise appears to protect one against bias (Kirk et al. 2011).

In addition, fMRI studies provided a very revealing difference between the art experts and the naïve subjects. In particular, there were important differences in the brain regions responsible for registering rewards and those for providing for the organism's final reaction to the first. The ventral medial prefrontal cortex (VMPFC) registers a sort of summative view of the rewards available, and in the naïve subjects, it was definitely affected by the pictures and their accompanying logos. The dorsal prefrontal cortex underlies the final judgment on action, and the reciprocity mechanism had created a very definite sense about value for it to pick.

The VMPFC of art experts, on the other hand, was not affected by the difference in reward attached to the accompanying logos. It is not that the DMPFC overcame the VMPFC; rather, the biasing mechanism failed to deliver its standard result. Interestingly enough, a few of the naïve subjects did not give biased judgments about the art, and the VMPFC was similarly less active as the art experts were.

New Problems

The research comparisons looked at so far do not provide us with many *definite* answers, but they raise some interesting questions. For example, can we find some similar bias-generating mechanism in the case of racism, sexism, etc.? Is the protective expertise in the two cases sufficiently similar to ground substantive generalizations from one class to the others. And, especially, are we seeing anything like a way to free us and our society of the scourge of racism?

We will start with an objection that is not as powerful as it may at first sight seem. Then we will move to a recent one that is potentially deadly. Finding out how to combat it will be illuminating.

We can think of the investigation so far as neuro-psychological. It takes the mental operations of individuals as the proper topic; its central question is about changing or modifying them. Our inquiry so far can be contrasted with an entirely different approach, that of collective action. The Civil Rights movement in the United States was a collective attempt to change structures in the society, in contrast to simply creating changes in attitudes toward Black persons. What we turn to now could be said to be more a sociological inquiry into whether what we have been looking at can result in changes in societies.

At least on the face of it, the prospects for change may not look very good. One problem is easily discerned. Given that racism affects nearly all of us, the acquisition of expertise is too limited to match the spread of bigotry in the society. In addition, some of the force of art expertise may well be due to the fact that art experts are to a considerable extent self-selected. Experts entering Montague's labs already have some idea of what discerning artistic judgment is; we have little reason to think that something similar holds in the naive cases.

One response to this problem is to see the training as the development of a select class, as opposed to giving us a potentially general group that can or should include us all. The key here is that expertise has a place in our society; given what people are willing to spend for expertise, it seems to have some initial credibility. Experts can move others to try to share some of their perspective. What we learn, it seems, is that while the acquisition of expertise about white privilege and black deprivation is not a universal solution, it is a promising addition to our discourse.

We will next look at some difficulties raised very recently in John Dixon et al (Dixon 2012a, b). There are two features of their discussion that are different from ours, and indeed from most discussions in philosophy. First of all, they take prejudice to be a matter of, in some general sense, not liking the targets of bigotry. Nonetheless, they seem aware that bigotry need not involve negative attitudes; for example, sexism

need not involve negative feelings about women. Hence, this difference seems not to impact our discussion very much. A second different is more significant. Their attention is not restricted to implicit attitudes. They include many cases, such as those of slave owners, which may not involve unconscious dislike at all; the dislike may be fully conscious. This difference is significant, since presumably, if we cannot put to rest conscious bigotry by some technique or procedure, we can expect unconscious bigotry to be even harder to modify or eliminate.

In discussing Dixon et al's arguments, we will start with evidence against what we have treated as a central claim of critical race theory, namely, that getting groups of people in a perspective sharing cluster will mitigate bigotry. Dixon et al take it as a matter of empirical fact that this does not necessarily work. They focus particularly on Dividio's research, which originally supported perspective sharing, but later questioned it (Hehman et al. 2012). They also look at actual social changes some countries have undergone. Forming such groups, even when they include perspective sharing, may not produce a significantly more egalitarian group. As with male and female relationships, the more powerful may want to preserve their position of power. The less powerful may remain resentful, while at the same time losing their sense that extensive change is needed. This result needs stressing since the relevant research has concentrated more on the attitudes of the oppressors than of the oppressed. Looked at simply from the dominant group's perspective, the success may seem more significant than it really is. The oppressed may be much less impressed.

Dixon's work makes a strong case that social institutions are not eliminated or even changed very much by making white people aware of complicity and white privilege. Historically, change springs from the discontent of those oppressed. Mitigating bias may in fact moderate the discontent enough to weaken a movement toward change; the good may genuinely be an enemy of the better.

For Dixon et al, there is a very important contrast then between a psychological change in individuals and a social change brought about through group action. Their strong case for this conclusion is very worrying, since it means that dealing with bias will be much more intractable than it may have seemed. There is, however, one more approach, one that is somewhat in between the psychological and the sociological.

Discussions of bias tend not to spend a great deal of time on another potentially moderating technique. While some bigotry is very visible in both its operations and its effects, a great deal operates outside of the public gaze. This is obviously true of much in the assessments in academia, yet these relatively small assessments may provide extremely important support of the very visible prejudice. Thus, if Blacks typically do not do well in academia, they may well end up in inferior jobs.

A second area where bigotry can operate quite quietly is health care. African-Americans in general receive inferior care across a lot of dimensions, from pain medication to investigative techniques and onto life-saving surgery. But the underlying decisions are relegated to a fairly private sphere occupied by doctor and patient. Hence, the discrepancy in healthcare between whites and blacks did not become the focus of a systematic study before the twenty-first century.

It is not clear why this is so, but it means that biased behavior does not receive the criticism it should. In fact, there is a good reason for holding back on the criticism: It tends not to do much good. People become highly defensive and inquiry tends to shut down. But if we concentrate on how structures in the society encode bigotry and criticize and change them, we may have a more promising route. We refrain from criticizing individuals and instead work on public critiques of more institutional facts.

To some extent, such mechanisms have been introduced in some areas. For example, it may be unlawful to withhold medical help on the basis of race. Many jobs forbid accepting gifts. Nonetheless, looking at a case with much more discussion than change, we can see that Oxford and Cambridge continue to have a very high proportion of students from the upper socio-economic groups. Hence, blaming and shaming something like possible institutional behavior may offer some hope, but it may need to occur in a context in which people are willing to learn how to do things differently. The possibility of future blaming and shaming may motivate learning, just as the censure on presents stops people from accepting them, at least when they think they could be found out. Nonetheless, while a group may be powerful, members of the group may not feel powerful enough to be happy to give up places in jobs and schools to members of the subordinate race. It is very hard to get such change genuinely welcomed.

Until we have more successful general social change, it seems we need to go back to where we started. We need to improve attitudes and welcome the relatively small changes they give us. Here we may find that knowledge really does make subjects much less naïve, as Harvey's work indicates. At least in some areas, we can make some progress, even if it is not as much as we would like. The coincidence between critical race theory and cognitive neuroscience may also be very useful.

Sex and Power: Why Sex/Gender Neuroscience Should Motivate Statistical Reform

91

Cordelia Fine and Fiona Fidler

Contents

Abstract

Towards the end of the last century, statistical reporting in medical research underwent substantial reform, with null hypothesis significance testing replaced with an estimation approach. Interestingly, this reform may have been largely motivated by the social costs of error within medical research, rather than simply scientific error per se. This chapter briefly reviews the benefits of the estimation statistical approach as a means to producing reliable information about nature and then describes how the current statistical method of null hypothesis significance testing specifically contributes to scientific error in sex/gender neuroscience. The potential social harm that can arise from such errors in this area of

research is then highlighted. It is suggested that sex/gender neuroscience may therefore provide a valuable model to motivate, on ethical grounds, statistical reform within the psychological sciences.

Introduction

Starting in the early 1980s, statistical reporting in medical research underwent substantial reform. Previously, analysis in medical research was dominated by null hypothesis significance testing (NHST), and the interpretation of findings was made primarily in terms of "statistical significance." Following many years of critique and debate, the medical literature then shifted to an estimation approach (effect sizes and measures of their associated uncertainty, e.g., standard errors and/or confidence intervals and, eventually, meta-analysis). The benefits of the latter statistical approach as a way of producing reliable information about nature – the fundamental goal of science – had been comprehensively and compellingly argued for decades prior to the reform. Interestingly, it was the social costs potentially arising from erroneous scientific conclusions in medicine – rather than simply scientific error per se – that most strongly motivated reform within the medical community (see Fidler 2011). Clearly, both false-positive and false-negative errors in medical research can give rise to significant harm, as when a treatment used by physicians is falsely believed to be effective (or falsely believed to be more effective than another treatment), or when a treatment that *is* effective in treating disease is not used because it is falsely believed to be ineffective. As Fidler (2011) has pointed out, scientific error in psychological research tends not to have the same potential scope for social harm as does medicine, in which error can literally be implicated in "life or death" outcomes. This in part may explain why advocates for a similar statistical reform in psychological science have not yet met with any significant success. However, Fidler notes that scientific error in psychological science is not cost-free, socially, and she discusses two examples in which erroneous conclusions – which would have been averted by the use of effect sizes, confidence intervals, and meta-analytic thinking – contributed to large social costs within the domains of employment aptitude testing and learned helplessness research.

One major category of psychological investigation with clear potential for social harm arising from erroneous scientific conclusions is research that makes comparisons between social groups. Erroneous scientific conclusions about the extent and origins of group differences may influence individual- and social-level attitudes, beliefs, behavior, social perception, self-perception, and social policy. This chapter, in keeping with its inclusion with the feminist section of a neuroethics handbook, focuses specifically on neuroscientific comparisons of males and females. However, similar arguments could potentially be made for other social group comparisons common in psychological work, including those based on age, socioeconomic status, and mental health status. In this chapter, it is argued that the current statistical method of NHST contributes to nontrivial social

harm arising from scientific error. This domain of research may therefore provide a valuable model to motivate, on ethical grounds, statistical reform within the psychological sciences.

The chapter begins, however, with a brief overview and contrast of the statistical approaches of NHST versus effect estimation.

Statistical Significance Versus Effect Estimation

In this section we briefly review a few of the well-known criticisms of NHST (for extensive reviews, see Cumming 2012; Kline 2004). We focus specifically on arguments that NHST increases the scope for false-positive and false-negative error and facilitates a conflation of statistical significance with practical or theoretical significance. This requires first clarifying the true meaning of a p value and/or the concept of statistical significance. A p value of less than 0.05 is commonly misinterpreted to mean that there is a less than 5 % probability that the results are "due to chance." In fact, the information provided by $p < 0.05$ is much more specific and less useful: A p value is the probability of observing a particular experimental result, or one more extreme, given that it doesn't actually exist in the world. To interpret p as the total probability of a chance result ignores the fact that p pertains only to the probability of a type I, or false-positive, error, and that it does not give information about the probability of a type II, or false-negative error. While the type I error rate is typically held constant at 5 %, the typical type II error rate may be closer to 50 % (we explain this further below in our discussion of statistical power). It is therefore a nontrivial mistake to assume that p captures the entire error rate.

Probably due in part to this common misconception within the research community as to the meaning of significant results, there is considerable overconfidence regarding the replicability of a significant result (Haller and Krauss 2002; Lai et al. 2012; Oakes 1986). The "replication fallacy" is the false belief that 1-p provides the probability of replicating a statistically significant effect. In fact, p values offer only very vague information about replication. For example, if you obtained $p = 0.02$ in an experiment and then replicated the experiment with new samples, making conservative assumptions, there is an 80 % chance that your next p will fall between 0.0003 and 0.30 (Lai et al. 2012). This extremely wide interval includes everything from "highly significant" (0.0003) to "don't look twice" (0.3). Most researchers severely underestimate this variability, expecting a range roughly half the size of the interval above (Lai et al. 2012). By contrast, reporting effect sizes and their associated uncertainty (e.g., confidence intervals) makes uncertainty explicit by providing a set of plausible values for the population effect. Such an approach does not preclude decisions: Confidence intervals can be used to reject or fail to reject the null hypothesis, when appropriate, by noting whether or not the null is captured. However, the main benefit of presenting results as effect sizes and confidence intervals, rather than test statistics and p values, is that it facilitates "meta-analytic thinking" (Cumming 2012). That is, it encourages us to compare the size of the

effects across studies, and note how the precision of estimates improves with each new data set, as opposed to making dichotomous decisions (significant/nonsignificant, accept/reject) on the basis of single experiments.

The misconception that a p value reveals the probability that a result is due to chance may also contribute to the overlooking of the possibility for false-negative errors. Statistical power is a measure of the probability that a given experiment will detect an effect of a certain magnitude as "statistically significant" if the effect really exists in the world. Statistical power depends on the size of effect (e.g., some difference of interest, a correlation or coefficient), the variability in the sample (e.g., individual differences), design features of the experiment to control for extraneous variation, sample size, and the alpha criterion set for statistical significance. In psychology and neuroscience, small sample sizes, modest effect sizes, and considerable individual differences (high amounts of variability) combine to create low statistical power in many experiments. While the probabilities of false-positive errors (i.e., p values) appear in over 95 % of articles in psychology journals, probabilities relating to false-negative errors (i.e., statements of statistical power) are reported in fewer than 10 % of articles (Cumming et al. 2007). Over the years, several diligent researchers have gone back through the literature and calculated the statistical power of published experiments. From these independent calculations, we know that the average statistical power of experiments to identify the medium-sized effects typical in many fields of psychology is around 50 % (e.g., Rossi 1990; Sedlmeier and Gigerenzer 1989). This means that conducting an average psychology experiment is roughly equivalent to flipping a coin, in terms of whether you get a statistically significant result or not (Hunter 1997). Button and colleagues recently estimated the statistical power of neuroscience studies to be even lower, at between about 8 % and 31 % (Button et al. 2013). Many statistically nonsignificant results are therefore not good evidence of "no effect" or "no difference." By contrast, effect estimation offers immediate information about precision (an equivalent concept to statistical power). A wide interval indicates a lack of precision; a narrower interval, relatively better precision. Confidence intervals contain a set of plausible values for the population effect, so wider intervals rule out fewer values as plausible. In other words, they give a less focused estimate of the effect. This means that studies with poor precision but nontrivial effect sizes are less likely to be misinterpreted as "no effect" (Fidler and Loftus 2009). It is hoped that this style of reporting would also mean that studies reporting trivial differences between groups are less likely to be misinterpreted as important and meaningful simply because they managed to scrape over the hurdle of statistical significance.

Furthermore, an average statistical power of 50 %, combined with many journals' biases towards only publishing statistically significant results, produces a skewed literature. The notorious "file drawer" is the typical fate for studies that failed to reach the significance threshold, even though there may be more of them. Publication bias pushes the number of false positives in the literature far beyond the 5 % rate one would expect from tests that report $p < 0.05$ – an outcome perhaps facilitated by the aforementioned overconfidence on the part of researchers of the replicability of a positive finding. If instead statistical reporting focused on effect sizes and intervals,

journal editors and reviewers – and researchers themselves – might pay greater attention to the precision of their estimates (as measured by interval width) and the size of the effects, rather than to the single probability of a type I error. If there is an equivalent publication bias that arises with estimation, then it is likely to be one that favors larger effect sizes and higher precision (statistical power). It's difficult to see how any such bias could create problems on the scale as those we see from the current bias towards statistical significance. In fact, it would seem to be exactly the sort of "bias" that many sciences desperately need.

There is a converse issue to the point that a nonsignificant p value is consistent with a sizeable true effect. This is that a significant p value does not guarantee a big and/or interesting effect or difference in the results. Because p values are a function of both sample size and effect size, neither can be read directly from a p value. Small, trivial differences can achieve statistical significance in a study with a large sample size and/or tight controls, for just the same reasons that sizeable important differences can fail to achieve statistical significance when the opposite conditions hold. The distinction between statistical significance and practical or theoretical significance is an important one. Practical and theoretical significance can be taken at face value – is the difference or effect big and important enough to make a practical difference in the world, and/or does it usefully advance scientific theory? Such questions belong in the discussion section of any experimental paper. But to enable a discussion of such questions, measures other than the statistical significance need to be reported. Effect sizes and their associated uncertainty intervals, either standard error or confidence intervals, are the commonly recommended alternatives (e.g., the last three editions APA Publication Manual have recommended reporting effect sizes, and the latter two have additionally recommended reporting confidence intervals). Effect sizes focus directly on the size of the difference, answering the "how big?" question, and lead naturally to questions of practical significance, "is a difference that big (or small) important?" and theoretical significance "what impact does a difference of that size have on our theory?"

Others have also pointed out how easily a conflation between statistical significance and practical or theoretical significance can arise. For example, Gigerenzer (1998, p. 5; see also Meehl 1978) identified null hypothesis significance testing as the tool primarily responsible for diminishing scientific theory in psychology, as it provides researchers with no incentive to formulate a quantitative hypothesis. Instead, the researchers' own unquantified hypothesis (the "alternative" hypothesis) is tested against a "nil" null hypothesis of no difference between the means or zero correlation. At best, the alternative hypothesis may be ordinal (that a difference will be *greater or less than* zero). In contrast, a truly quantitative hypothesis would predict, for example, whether a difference would be greater or less by a factor of three or a factor of 20. Theory would guide the specification of those quantities, and the two competing hypotheses would be pitted against each other. It is extremely rare to see such quantitative hypotheses in psychology (Cumming et al. 2007). An institutionalized methodology that does not encourage researchers to think quantitatively about their hypotheses is unhelpful in terms of progression of scientific theory.

The problem above is not limited to psychology and neuroscience, but it is limited to disciplines that over-rely on statistical significance. In sciences that do not, research questions are posed quite differently. For example, a chemist would not ask: “Is the boiling point of this new substance significantly different from zero?” (Cumming and Fidler 2009). Rather, they would start by empirically estimating the boiling point and quantifying the uncertainty of their estimate. The business of subsequent experiments would be to refine the estimates, with each new data set improving the precision. Theory would direct testing quantitative estimates of different boiling points under different conditions.

The issues discussed above concerning false-positive errors, false-negative errors, and the conflation of statistical significance with practical or theoretical significance can be readily applied to sex/gender neuroscience. Each is discussed briefly below.

False-Positive Errors

False-positive results and publication bias are issues in all areas of behavioral science (for recent discussions, see Fanelli 2012; Simmons et al. 2011; Yong 2012). However, it has been argued that this problem is particularly acute for neuroscientific (in particular, functional neuroimaging) investigations of sex/gender difference, and the arguments below draw extensively on previous discussions in Fine (2012b, forthcoming). As noted long ago (Maccoby and Jacklin 1974), false-positive errors are exacerbated in the sex/gender differences field to the extent that male/female comparisons are routinely made. The simplicity and “obviousness” of testing for differences between males and females, together with a publication bias towards positive findings, creates good conditions for false-positive findings of difference to be reported, while true-negative findings are not. There is currently no way of knowing whether researchers who do not report sex comparisons have nonetheless tested for them, and it is not known how common such practices are. However, Kaiser and colleagues (Kaiser et al. 2009, p. 54) have argued that because sex is a primary and ubiquitous social category, classifying participants by sex is a “natural default” and is “seemingly effortless and obvious in brain research.” Wallentin (2009), moreover, has pointed out that functional neuroimaging studies are especially vulnerable to false-positive sex/gender results, due to nuisance variables (like breathing rate and caffeine intake) that affect the imaging signal, and that this is particularly an issue when sample sizes are small. In line with this, Thirion et al. (2007) demonstrated the low reliability of fMRI studies with samples less than 20, due to large intersubject variability.

A good demonstration of these issues is provided by investigations of the long-standing hypothesis that the male brain is more lateralized than the female brain for language processing. A heavily cited early fMRI investigation of this hypothesis gave 19 men and 19 women phonological, orthographic, and semantic processing tasks to perform while being scanned (Shaywitz et al. 1995). Left lateralization of inferior frontal gyrus activity was found in men for phonological processing, but no

such lateralization was observed for women. No sex/gender differences were observed for orthographic or semantic processing. Subsequent data have been mixed and, overall, unsupportive of Shaywitz et al.'s positive finding: Two recent large meta-analyses of functional neuroimaging studies of language lateralization failed to find evidence for sex/gender differences (Sommer et al. 2004, 2008). Further demonstrating the need for skepticism with respect to the reliability of any one finding of a sex/gender difference, particularly when sample sizes are modest, Ihnen and colleagues found that the sex/gender differences in brain activity observed in a group of 13 men and 13 women during language processing failed to generalize to similar language tasks within a second group of 10 men and 10 women. Moreover, identical analyses of the same participants "discovered" brain activation differences between randomly created groups matched on sex, performance, and obvious demographic characteristics (Ihnen et al. 2009).

Thus, although in theory the probability of false-positive errors should remain the same regardless of sample size, a combination of publication bias, data noise, large intersubject variability, and considerable scope for researcher discretion about the construction of dependent variables may mean that, in practice, this is not the case. This is problematic since, due to the expense of conducting such research, small sample sizes are common in functional neuroimaging investigations of sex/gender. A recent analysis of such studies published in 2009 and 2010 found that it was as common for studies to have fewer than 10 participants in each of their groups of interest (in many studies the sexes were further subdivided, for example, by clinical status or experimental condition) as it was to have more than 20 participants in each experimental cell (Fine 2012b). This underlines yet further the importance of meta-analyses in attempting to establish the size of effects, as individual studies, particularly very small ones, should not in themselves be the basis of theory acceptance or rejection.

Reporting effect sizes and uncertainty intervals as the primary analysis does not make the problems of small sizes, noisy data, or large individual differences go away, but it would help make those problems transparent. For example, we are better able to judge when a statistically nonsignificant effect is simply the product of low power when results are presented as effect sizes and intervals rather than p values alone (see Fig. 91.1). We are similarly better equipped to judge when a result is statistically significant, but the best estimate is too close to zero to be of genuine interest. Under conditions of small sizes, high noise, and large individual differences, intervals will usually be extremely wide. This immediately tells us precision (statistical power) is low. Seeing a figure with error bars that span a very wide range of all possible results would, we hope, encourage caution in the interpretation of statistically nonsignificant results. It would draw attention to the fact that although some intervals fail to include a difference of zero (reflecting a statistically significant result), they may stop only a fraction shy of zero and still be extremely wide. The great advantage of confidence intervals then is that they bind together information about type I and type II errors: 5 % is the total error rate (or chance the interval will miss the true value), and the width of the interval can't be left out or ignored in the way that statistical power routinely is.

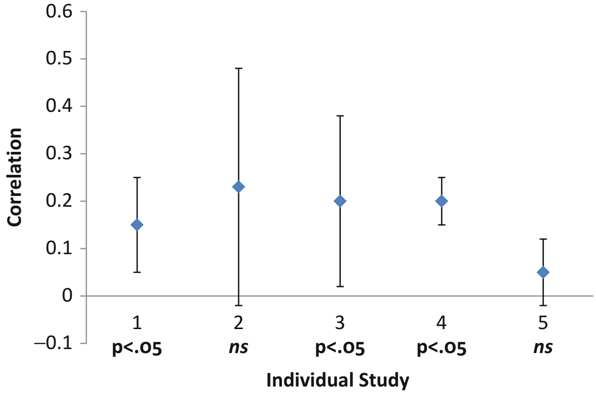

Fig. 91.1 The statistical outcome of five fictional studies comprising a hypothetical research literature. Results of individual studies are reported as correlations, with 95 % confidence intervals. The corresponding NHST result is reported below the horizontal axis. Intervals which cross zero correspond to statistically nonsignificant (*ns*) results at the 5 % level

Imagine the five studies in Fig. 91.1 comprise the existing literature for a question about correlation between biological sex and lateralization of brain activity. Examining only the effect sizes (in this case, correlations) and confidence intervals, the salient message is one of *consistency* of results – the correlations are very nearly the same in each study. There are, however, differences in precision – some intervals are clearly much wider than others. The widest ones (studies 2 and 5) cross zero and are therefore statistically nonsignificant at the 5 % level. If these five studies were reported in terms of statistical significance, then the message would *not* be one of consistency. Rather we see claims of statistical significance (study 1) followed by nonsignificance (2) followed by significance (3 and 4) and nonsignificance again (5). Reviewers of the literature would most likely call for further studies, exacerbating the problem. Debate would be created where in fact none should exist. The current bias in publishing would see study 3 accepted for publication, but study 2 excluded, simply because the latter scrapes over zero and the former narrowly avoids doing so. Study 5 would also be excluded from publication, even though it has relatively high precision compared to others that would be accepted (e.g., 1 and 3). The language of statistical significance allows the bias to keep operating, by creating false dichotomies between, for example, study 2 and 3 which, if they looked at different kinds of language processing, might create a red herring in terms of future research directions. Without a primary focus on *p* values, and the accompanying language of statistical significance, the illusion that any of correlations differ from each other in a meaningful way disappears.

Figure 91.2 shows another set of five fictional studies comprising a hypothetical research literature. In this case, the true population correlation is less than 0.1 and so very unlikely to be theoretically or practically meaningful. Now imagine this is a domain in which publication bias is at play. The nonsignificant studies (studies 2, 3, and 5) would be excluded from publication, even though in every case they have higher statistical power (higher precision, narrower intervals) than the statistically significant studies (studies 1 and 4). The two significant studies leave a slightly inflated view of the correlation, although it remains very small. Even so, if those

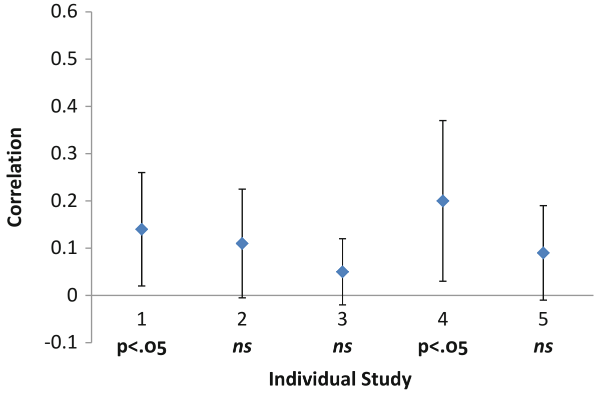

Fig. 91.2 The statistical outcome of five fictional studies comprising a hypothetical research literature, where the true correlation is trivial (i.e., 0.1). The outcome of individual studies is reported with 95 % confidence intervals. The corresponding NHST result is reported below the horizontal axis. Intervals which cross zero correspond to statistically nonsignificant (*ns*) results at the 5 % level

studies are reported primarily in terms of statistical significance, then those small correlations are susceptible to being misinterpreted as meaningful. If instead the actual correlations with their very wide error bars are observed, narrowly avoiding zero, there may be less chance of misinterpretation. There may also be greater awareness of sampling error and suspicion regarding what lies in file drawers and whether replications would also scrape over the line.

In addition, it is not only the production of false-positive errors that is of concern in this area of research – it is also the persistence of false-positive claims in the research literature. An analysis by Fine (2012b) of all 2009 and 2010 citations of the original Shaywitz et al. (1995) finding found that 43 of the 75 (57 %) cited the Shaywitz study without referring to the existence of any contradictory data. Of the remaining 32 citations, 11 (15 % of the total) either failed to cite either of the Sommer and colleagues' meta-analyses or did so in a way that was misleading. A further nine studies cited one or both meta-analyses, but in a way that gave no indication that, through virtue of its status as a meta-analytic study, it lay claim to being a more reliable source of information than Shaywitz et al. Thus, just 12 of the 75 (16 %) studies that cited the Shaywitz finding also cited the work of Sommer and colleagues in a fully informative way (even if the latter's conclusions were disputed). Meta-analysis and the estimation approach go hand in hand. Almost all meta-analysis requires effect sizes of individual studies as their primary input. Furthermore, reporting and interpreting effect sizes and confidence intervals helps researchers think meta-analytically about the contribution of each new study to the existing body of knowledge. They are less likely to see illusory inconsistencies in literatures, such as in the five fictional studies examples (Coulson et al. 2010). For example, one response to Sommer et al. (2004) negative conclusion was the suggestion that males are more lateralized specifically for passive listening to stories (Kitazawa and Kansaku 2005). However, this was made on the basis of two small statistically significant studies using this dependent variable. Such a suggestion might be compelling within the context of a qualitative review that merely assessed significance versus

nonsignificance, but in this case Sommer and colleagues were able to note directly in response that positive findings were much more likely to be observed in small studies (Sommer et al. 2005).

False-Negative Errors

Feminist critiques of neuroscientific investigations of sex/gender difference have been particularly concerned with false-positive errors and the emphasis on difference over similarity (e.g., Kaiser et al. 2009). However, it is also the case that male/female behavior is not completely overlapping in all domains, and the sexes also differ in incidence of mental disorders such as depression and autism. Such differences have, understandably, motivated arguments for the importance of investigating sex differences in the brain (Cahill 2006, 2010; McCarthy et al. 2012). However, the neural basis of such differences will not be readily identifiable in humans. The substantial overlap of male and female distributions on the majority of psychological and behavioral measures has been persuasively argued for quantitatively (Hyde 2005). That male and female brain characteristics are also significantly overlapping, even where statistically significant sex differences have been identified, has also been noted (e.g., Jordan-Young 2010). Moreover, Joel (2011, 2012) has recently argued, on the basis of nonhuman animal neuroscientific research, that although biological sex influences brain development as it occurs in interaction with environmental experiences, it is not in any simple way that generates distinctive "male" and "female" brains. Joel argues instead that brain characteristics take the form of complex, idiosyncratic "gender mosaics" within each individual. This argument highlights the point that, while no doubt the brain is not infinitely malleable, neural circuitry develops through, and is altered by, experience. The importance of this with respect to sex/gender in the brain comes from the fact that gender, as a powerful and pervasive social phenomenon, ensures that a person's biological sex will influence the experiences (such as material, social, and mental) she or he encounters. This will, in turn, leave neurological traces (see, e.g., Fausto-Sterling 2000, 2005; Kaiser 2012 for arguments for the inextricable intertwinement of sex and gender in the body and brain), and such experiences will vary across individuals.

These points raise the important conceptual question of whether it makes sense to try to identity an effect size of biological sex on brain structure or function. But whatever precise research question is pursued, uncovering what are undoubtedly highly complex interactions against a background of noise and considerable individual differences will require more complex experimental designs. As the complexity of design increases, with multiple groups and multiple comparisons, so too must the sample size if adequate statistical power is to be achieved. This would point to the conclusion that the success of future neuroscientific research into sex/gender may depend on the extent to which the field is sensitive to concerns regarding statistical power. Currently, considerable intersubject variability, together with mostly modest behavioral

effect sizes, suggests that typical functional neuroimaging studies may lack the statistical power to detect any true sex/gender effects that may exist – a fact that is obscured by the use of NHST.

Practical and Theoretical Significance

In an analysis of all 2009 and 2010 functional neuroimaging investigations of sex/gender differences, Fine (2012b) found that none of the 39 studies tested predictions derived from well-specified neurocognitive accounts of the sex-/gender-modulated mental processes involved in the behavior of interest. Rather, the studies tested the null hypothesis that no sex differences in brain activity would be observed – either in any part of the brain or in particular regions suggested by prior research. Such a research strategy makes a very limited contribution to theoretical progress, for reasons discussed previously and, in addition, because the functional significance of a sex difference in brain activity is obscure (see Fine 2010; Hoffman 2011). Moreover, the absence of well-developed and empirically supported accounts of the relationship between brain activity and mental processes readily enables interpretations of findings that draw on gender stereotypes to fill in the substantial gaps in neuroscientific knowledge. In the 2009/2010 sample, approximately two-thirds of the studies speculated a functional significance to their finding of sex differences. The influence of gender stereotypes was especially clear where such speculations were consistent with gender stereotypes but inconsistent with the researchers' own relevant behavioral data, which occurred in a number of cases. In other words, there appears not to be a strong requirement for studies to demonstrate either theoretical or practical significance, only statistical significance.

Theoretical and practical significance requires interpretation of results in terms of their effect sizes, not their p values. Such interpretation requires knowledgeable judgment in context, which may be harder than an automated judgment of p relative to an arbitrary criterion, usually.05. But such judgment is accepted as the norm in relation to numerous other aspects of planning and running research; we need to accept it as necessary also for the interpretation of results. Readers may, of course, disagree, but effect size and CI information provide full information for an informed discussion about the results and what they can justifiably imply. That is, one justifies why a 0.6 s reaction time difference or a 5 percentage point difference between males and females in a difference in brain activity between a control and experimental condition is meaningful, large, or important, not why $p = .03$ matters. Any given effect size (e.g., 5 percentage points) may or may not be statistically significant, depending on the other conditions of the experiment, but whether a difference of that size is important in that context will remain constant. Effect sizes underpin theoretical and statistical significance, and confidence intervals give us a plausible range for the effect size. We can then determine whether that range is sufficiently narrow (includes all important and very important effect sizes) or inadequately broad (includes all important effect sizes but also all unimportant ones).

Social Harm from Scientific Error

As argued in Fine (2012a, 2013), it can be expected that claims about sex/gender differences in the brain and their implications for how and why males and females behave differently will have psychological consequences. Hacking (1995, p. 351) has described "looping" or "feedback effects in cognition and culture," whereby the causal understanding of a particular social group changes the very character of the group, leading to further change in causal understanding. Similarly, Choudhury and colleagues, referring specifically to the social impact of neuroscience, have argued that the representation of "brain facts" in the media, policy, and lay perceptions influences society in ways that can affect the very mental phenomena under investigation (Choudhury et al. 2009). The original finding of persuasive power of brain images (McCabe and Castel 2008) has recently been disputed both qualitatively (Farah and Hook 2013) and quantitatively in a recent meta-analysis (Michael et al. 2013). However, "brain facts," regardless of the presence or absence of brain images, may enhance how satisfactory or valuable lay people judge scientific explanations of psychological phenomena to be (Michael et al. 2013; Morton et al. 2006; Weisberg et al. 2008). The enhancing effect of neuroscientific accounts may be facilitated by the way in which neuroscience findings tend to be presented in the popular media (Racine et al. 2005, 2010).

Three lines of research offer insights into the psychological effects of claims about sex differences in the brain and, in particular, implications from such research that gender differences are "essential" (see Fine 2012a). First, preliminary evidence looking at the effects of information about the reasons for gender differences in mathematics on performance suggests that a spontaneous assumption that gender differences are "biologically" caused may have detrimental effects on performance (Dar-Nimrod and Heine 2006; Thoman et al. 2008). Second, both the endorsement of "biological" explanations of gender differences and exposure to such accounts are associated with greater endorsement of gender stereotypes (Brescoll and LaFrance 2004; Martin and Parker 1995) and more stereotypical self-perception (Coleman and Hong 2008). This is merely one example of a general tendency for biological essentialist beliefs to be associated with endorsement of a wide variety of social stereotypes (Bastian and Haslam 2006). Third, there is evidence that a stronger weighting of genetic influence on behavior is associated with greater moral tolerance of the social status quo (Dambrun et al. 2009; Keller 2005). It has been argued that the belief that differences between social groups are biologically essential naturalizes inequality and serves a system-justifying function, both in general (Yzerbyt et al. 1997) and specifically in relation to gender (Bem 1993). Supporting such a motivated system-justifying basis for biological essentialist accounts of gender, Morton and colleagues found links between essentialist beliefs and sexism in men only and only when women were presented as gaining ground on men. Conversely, they also showed that scientific claims about gender influenced endorsement of hierarchy legitimizing beliefs and attitudes (Morton et al. 2009).

In short, erroneous scientific claims are not cost-free. “Brain facts” about sex differences make their way into popular culture where they may influence the very mental phenomena under investigation. In this way, independent of their truth, erroneous claims can affect people’s lives and society in self-fulfilling ways.

Conclusion

There is no “perfect” way to conduct scientific research nor any ideal statistical approaches. In fact, what matters most is sound statistical reasoning, rather than any specific tool. However, for the reasons discussed here, current usage of the single technique of NHST puts scientific reasoning at risk and facilitates the production of research literatures readily contaminated by illusory inconsistencies, false positives, false negatives, and the conflation of statistical and theoretical/practical significance. Other techniques, such as estimation, may promote reasoning simply because they are more transparent and have not been ritualized to the same extent. In this chapter we have provided a specific example of how a replacement of NHST with effect estimation would have a number of beneficial scientific effects within the domain of sex/gender neuroscience. In particular, it would reduce the scope for the production and persistence of false-positive errors, draw attention to the low chance researchers have of identifying real sex/gender effects due to low statistical power, and facilitate more strongly theory-driven research hypotheses. Such changes would not only be scientifically advantageous but also reduce the potential for social harm arising from erroneous scientific claims about sex differences in the brain. That the internal goal of science is not being well served by current neuroscientific investigation of sex differences should create consternation in the scientific community even in the absence of social concerns about harmful effects of erroneous claims about sex differences in the brain. Scientists are certainly responsible for the quality of the evidence they produce, and their research decisions – including statistical approach – impact the probability of error. We suggest here that scientists may also wish to consider the social costs of potential error. The example of medical research suggests that it is these social consequences that, in the end, may be the most persuasive in bringing about beneficial statistical reform that will, in turn, help the progress of science.

Contents

Abstract

Contemporary neuroscience has become a poster child for medical sciences and has gained tremendous salience in the public eye. The growth of neuroscience has resulted in multiple developments, generating a flow of new research, allowing the exploration of new research domains beyond the traditional frontiers of medical science, and enticing the younger generations to train in neuroscience. At the same time, the public, in its plural manifestations, has become eager to engage with the advances of neuroscience. In this introduction to this section of the Handbook, I underscore and discuss briefly three aspects of the relationship between the media and neuroethics, which illustrate the importance of the media. I then introduce three original contributions dealing with the media and neuroethics. Hopefully, readers of this book will find these contributions stimulating and that the latter will encourage more needed work in this area.

Introduction

In many ways, contemporary neuroscience has become a poster child for medical sciences and has gained tremendous salience in the public eye. Starting in the 1960s and 1970s, the international neuroscience community has grown almost steadily. International societies such as the Society for Neuroscience and the International Brain Organization have seen their memberships reach considerable proportions. This growth has resulted in multiple developments, such as generating a flow of new research, allowing the exploration of new research domains beyond the traditional frontiers of medical science, and enticing the younger generations to train in neuroscience. At the same time, the public, in its plural manifestations, has become eager to engage with the advances of neuroscience. A cascade of contributions written for the general public has approached the diagnosis and treatment of neurological and psychiatric illness as well as explored the application of neuroscience knowledge to education, law, and the psychology of everyday life (e.g., creativity, parenting, memory). It is therefore no surprise that the public salience of neuroscience has intimate and multifaceted connections to the field of neuroethics: As neuroscience ventured closer and closer into practical and daily life, it has generated questions about its impact on human values. In the following, I underscore and discuss briefly three aspects of the relationship between the media and neuroethics to introduce this section of the *Handbook*.

Public Notoriety and Visibility of Neuroscience as a Precondition for Neuroethics

First, neuroethics as we now know it would not have emerged as a distinct endeavor were it not for the public notoriety of neuroscience itself. (This does not mean that ethical challenges in neuroscience would not exist without neuroethics or that other responses – other than neuroethics – to these challenges would have not flourished). Scholars and others are keenly aware that advances in neuroscience have percolated to the broader public and public domain, and are therefore also aware of their potential implications. Likewise, ethicists and others have less interest in working on topics which have no bearing on public opinion and behavior (unlike the use of neuropharmaceuticals for enhancement of performance, or non-referred purchase of neuroimaging services), which touch the public directly.

Neuroethics as a Step in the Development of a More Open and Public Bioethics

Second, the field of neuroethics emerged at a time when bioethics itself was opening to empirical research and reconnecting with an impetus found at the beginning of its history, i.e., to consider non-expert perspectives (e.g., see chapter of the Belmont Report dealing with public attitudes toward science and Racine (2010) for a review). Because the impact of neuroscience was potentially far-reaching, there were early

calls in neuroethics supporting the need for public dialogue, public engagement, and general increased public understanding of neuroscience (Safire 2002; Leshner 2005). Arguments were made that the challenge of the interpretation of neuroscience findings, especially those bearing on cognitive processes and personality, brought a conflict between the manifest and the scientific images of man (read: humankind) following Sellars' distinction (Sellars 1963). The public's perspectives and interpretations in the forms of neuroessentialism or neurodeterminism are therefore of importance, since they capture an interpretation of how the manifest and scientific images are negotiated (Illes and Racine 2005). Whether these interpretations are justified or not, or based on solid neuroscience and sound philosophy, the public's deciphering of them would matter as such and would need to be considered.

Neuroethics as a Hub of Research on Media, Science, and Public Engagement

Third, and in response to calls for public engagement, neuroethics has given considerable attention to topics related to public engagement, public understanding of neuroscience, and the media. In a review focused on the early years of neuroethics, this topic was found to be frequent in peer review literature and also in print media reports about neuroethics (Racine 2010). The number of relevant papers is of course too numerous to list or review here (a more comprehensive review has been offered elsewhere (Racine 2011)), but a few important results illustrate domains where progress has been made (see Table 92.1).

Contributions on Neuroscience and the Media

The following contributions in this *Handbook of Neuroethics* by Forlini and colleagues, Krahn, and Savane offer a clear representation of recent work in the area of media and neuroethics and address some of the points discussed above. Forlini and colleagues in a chapter entitled ▶ "Popular Media and Bioethics Scholarship: Sharing Responsibility for Portrayals of Cognitive Enhancement with Prescription Medications" (Chap. 93) approach the roles of the media in debates about cognitive enhancement using prescription medications. They examine how the media may have had upstream implications on bioethics scholarship as well as downstream consequences (e.g., on prevalence rates for the use of prescription medications). Their analysis highlights some problematic aspects of media coverage of cognitive enhancement and how some of these trends have percolated to academic scholarship without sufficient scrutiny. They call for greater awareness of the impact that the media and bioethics scholarship have on such debates and identify questions to address with respect to conventional and social media in the context of cognitive enhancement.

Krahn in his chapter titled ▶ "Traumatic Brain Injury and the Use of Documentary Narrative Media to Redress Social Stigma" (Chap. 95) introduces a critical note about how neuroethics is unfortunately often depicted narrowly by its critiques to exclude

Table 92.1 Illustrative (non-exhaustive) areas of research related to neuroethics in media

Media content dissemination and public portrayal of neuroethical issues
Examination of neuroethical questions and topics such as cognitive enhancement (Coveney et al. 2008; Williams et al. 2008; Forlini and Racine 2009; Partridge et al. 2011)
Examination of media portrayal of neuroscience technologies and neuroscience results such as fMRI and DBS research and related ethical discussion (Racine et al. 2006, 2007a, 2010; O'Connell et al. 2011)
Examination of media content regarding ethical aspects in neurological disorders and mental illness such as coma (Wijdicks and Wijdicks 2006a, b) and the vegetative state (Racine et al. 2008; Striano et al. 2009)
Media impact and understanding of behavior regarding neuroethical issues
Examination of practices and regulatory issues surrounding direct-to-consumer advertising regarding neuroimaging, dietary supplements, and neuropharmacology (Illes et al. 2003; Illes et al. 2004; Racine et al. 2007b)
Examination of the impact of media content on attitudes toward cognitive enhancement (Forlini and Racine 2012)
Examination of the impact of neuroessentialism and neurorealism on neuroscience explanations (McCabe and Castel 2008; Vohs and Schooler 2008; Weisberg et al. 2008)
Nonconventional media and multidirectional communication in neuroethics
Proposal of models for public engagement regarding neuroethical issues (Blakemore 2002; Rose 2003; Racine et al. 2005)
Experiences in multidirectional communication (Illes et al. 2005)
Proposal for training programs in neuroscience communication with relevance to neuroethics (Illes et al. 2010)

considerations related to culture. Inspired by a pragmatic view of neuroethics where public and intercultural neuroethics hold major importance, he offers an insightful analysis of stigma and public misunderstandings in the context of traumatic brain injury where "hidden disabilities" and the "brain" aspect of the injury and related impairments can augment stigma. Krahn then explores a series of novel approaches such as narrative-based strategies and new media to combat sigma.

Savane presents in her chapter, appropriately titled ▶ "Neuroethics Beyond Traditional Media" (Chap. 94), an overview of nonconventional media and public engagement. She focuses on the rich and diverse European neuroscience environment which has witnessed a series of national and European-level initiatives such as *Brains in Dialogue* and *Meeting of the Minds*. These initiatives and the discussion by Savane invite us to consider how public engagement can be part of every aspect of neuroethics: from defining and understanding the issues, to envisioning responses. Although multidirectional communication and public engagement initiatives do not replace traditional media, they respond to a need to broaden public discussion and allow the mutual enrichment of perspectives.

Future Directions

The chapters on media and public engagement in this book meaningfully contribute to the critical investigation and discussion of media in neuroethics and

neuroscience. Still, there are important questions which have been untapped in our field. For example, Table 92.1 presented above is silent on the process of “media content development.” This is an essential area in media studies that has not been fully considered in the context of neuroethics. For example, how is media coverage of neuroethics developed? How do neuroethicists engage with the media and why? How do journalists understand neuroethics and what prompts them to write about these topics? Who gets to talk and obtain coverage and who does not? How are decisions to include or exclude ethical considerations from the reporting of neuroscience research made? These are questions that would call for further attention to understand how the field of neuroethics can contribute to an enlightened public dialogue and a strong representation of matters of ethics in public discussions. Media analysis and discussions about public engagement have been rather well represented in neuroethics scholarship; yet, there is much to be done to push the field further both in scope and depth. In terms of scope, we need replication studies and further comparative work to build on initial studies. In terms of depth, we need to better understand, based on theoretical and empirical contributions, the full cycle of media information development and its relationship to neuroethics. This would involve approaches such as normative models clarifying the responsibilities of neuroscientists in public communication, conceptual clarifications of the impact of public information on neuroethical issues, and tighter empirical work to understand the precise impact of public information on behavior. I hope that readers of this book will find the following contributions stimulating and that the latter will encourage more work in this area.

Acknowledgments The author would like to thank Mr. John Aspler and Mrs. Allison Yan for feedback and assistance on a previous version of this manuscript. Support for the writing of this introduction comes from the Canadian Institutes of Health Research (New Investigator Award) and the Social Sciences and Humanities Research Council of Canada.

Abstract

The use of prescription medications for the cognitive enhancement of healthy individuals has been a captivating and contentious subject in the media and in the bioethics literature. This chapter provides an overview of the roles the media have played in reporting features of the nonmedical use of prescription medications by healthy individuals for enhancement and the influence the media have exerted on academic discourses. We note the broadening of media coverage from trend reporting to taking on research questions of the prevalence and efficacy of cognitive enhancement. We also reflect on the emergent contribution of messages via social media in online discussions about cognitive enhancement. Messages from traditional and social media are often based on anecdotal evidence and may perpetuate misrepresentations of cognitive enhancement especially when referenced by academic researchers. Such misrepresentations may harbor underlying normative messages that can influence the behavior of individuals. The different forms of media and academic bioethics share a responsibility to portray cognitive enhancement in a light that reflects current evidence and does not encourage the nonmedical use of medications based on anecdotal experiences.

Introduction

The use of prescription medications by healthy individuals for cognitive enhancement has been a captivating subject in the media and in the bioethics literature. The scientific and ethical underpinnings of cognitive enhancement have polarized the perspectives of contributors to the bioethics discussion, leaving ample room for debates on scientific evidence and ethical principles (Forlini and Racine 2013). Over the last 10 years, a significant number of newspaper articles and special reports have captured the attention of readers as well as other audiences via television and radio reports or discussion over social media (Forlini and Racine 2009b; Partridge et al. 2011; Wade et al. under review; Williams et al. 2008). Cognitive enhancement is often *reported* as a phenomenon growing in prevalence and complexity. Through various forms of media coverage, journalists are seeking to relay information about and expose the underpinnings of a new or contentious phenomenon (Seale 2003). In some instances, the search for answers in media reports has blurred the boundaries between investigative journalism and research. A few studies have examined the specific features of media coverage on cognitive enhancement (Forlini and Racine 2009b; Partridge et al. 2011; Wade et al. under review; Williams et al. 2008). This chapter aims to critically examine some of the features of media coverage on cognitive enhancement in order to reflect and comment on the role it has played upstream in the bioethics debate and downstream for public understanding.

How Has Cognitive Enhancement Been Represented in the Media?

Within the following section of this chapter, we identify and discuss three distinct features of media coverage on cognitive enhancement. These features are related to the way journalists engage with the issues in the cognitive enhancement debate. In this respect, we examine: (i) the traditional reporting of a trend, (ii) the transition of the journalist into a "researcher" to fill gaps in knowledge, and (iii) the influence of social media that is shifting the ways in which information and experiences are disseminated and consumed.

Media Coverage Reporting a Trend

In reporting a trend, the journalist relies on already published material or other observations. Early reports on what is now more commonly referred to as cognitive enhancement were based on prevalence studies carried out on US college campuses in the early 2000s (Babcock and Byrne 2000; Graff Low and Gendaszek 2002; McCabe et al. 2004; Teter et al. 2003). These media reports addressed the broader topic of stimulant abuse and sometimes included related aspects of the medical profession and campus culture. Of particular interest in examining trend reporting is the newspaper coverage from the UK on this topic. These newspaper articles characterized the nonmedical use of stimulants for enhancement purposes as a distinctively North American phenomenon that would eventually catch on in the UK as well (Forlini and Racine 2009b). Interestingly, at the time, no study existed to confirm that stimulant use for enhancement was not already occurring in the UK and prevalence figures in the UK generated by academic research have still not been published. The trend reporting proved to be speculative by portraying cognitive enhancement as an epidemic based on data from another cultural context. The US prevalence numbers have since been questioned as to their robustness in supporting the portrayal of cognitive enhancement as a widespread or growing phenomenon (Lucke et al. 2010). In this regard, journalists relied on academic sources whose interpretations were already enthusiastic. Furthermore, in reporting cognitive enhancement as a trend spreading to the UK, journalists ran the risk of potentially accelerating the spread of nonmedical stimulant use. A study conducted by Dasgupta et al. (2009) demonstrated a temporal association between reports in the news media on prescription opioid use and overdose mortality. With news media reports on opioid abuse consistently preceding peaks of poisoning mortality, the article begs the question of whether the news media might have fueled an epidemic of opioid overdoses (Dasgupta et al. 2009). At this point, any influence that the media may have had on prevalence of stimulant use by university students in the UK cannot be verified. The perceived spread of a trend such as cognitive enhancement could have been an informative avenue for academic research into either the actual prevalence of stimulant use among students in the UK or perhaps

a study of whether this type of trend would be troubling to the public in that region. At the time, the trend reports from the UK media might have served as cues for valuable research to characterize an oncoming phenomenon.

Another feature of trend reporting has been the use of anecdotal reports to introduce the topic of nonmedical stimulant use by students. The experience of university students who used stimulants with the intention of enhancing their academic performance has acted as a cornerstone of trend reporting. Reports based on anecdotal evidence provide an experiential anchor to the phenomenon of cognitive enhancement. Partridge et al. (2011) showed that anecdotal evidence was the basis of 15 % of newspaper articles they sampled. Anecdotal evidence of academics using modafinil as a cognitive enhancer also fueled the premise of a commentary published in *Nature* (Sahakian and Morein-Zamir 2007). Using anecdotal evidence in media reports can be problematic on two fronts. First, comments from members of the stakeholder groups in a qualitative study showed that some important pieces of information were deemed to be missing from newspaper articles (i.e., scientific data, risks and benefits, prevalence) (Forlini and Racine 2012). Given the space constraints of some media formats, it would be inappropriate if anecdotal evidence is privileged over academic references. Second, anecdotal evidence explaining the particular experience of users often reveals some of the specific details of how people go about using stimulants and other medications for enhancement. For example, media articles may explain how and where students are procuring medications; imply effective dosages for cognitive enhancement; report the (side) effects that can be expected; and convey resounding praise for enhancers by quoting users. In addition to raising awareness about the cognitive enhancement trend, media reports including anecdotal evidence may inadvertently provide crucial details which would enable readers to do the same. These problems are not confined to media reporting. Academic research on any one of these aspects of prevalence could yield and disseminate the same type of information. This situation highlights the shared responsibility of journalists and academics in walking the fine line between informing and encouraging when reporting on or investigating cognitive enhancement.

A Journalistic-Empirical Approach to Media Coverage

The second feature of media reports on cognitive enhancement concerns the convergence of journalism and research. Instead of relaying information about a trend, some journalists have undertaken investigations that further characterize elements of cognitive enhancement that remain elusive. The prevalence of cognitive enhancement and the efficacy of medications in healthy individuals are of particular interest for these types of reports. In this way, journalists are gaining firsthand knowledge of prevalence in their environment or verifying the anecdotal reports of the effects of stimulants and other enhancing substances on their personal activities. These forms of data are often more accessible to lay audiences than publications in academic journals and would speak to local contexts. However, the results of these journalistic-empirical investigations can lack in the expertise, ethics oversight, and rigor that academic research abides by.

Journalists Researching Prevalence

Much of the media and academic discourse remains centered on the use of stimulants by university students where prevalence studies state that between 2 % and 11 % are using cognitive enhancement to improve academic performance (Franke et al. 2011; Racine and Forlini 2010). However, within the academic debate, these prevalence figures have been subject to much criticism on the basis of their methodology and their interpretation of these findings (Hall and Lucke 2010; Lucke et al. 2010). One of the major limitations of current prevalence studies on the nonmedical use of prescription stimulants for recreation and enhancement is their ability to serve as indicators of general prevalence. They are focused mainly on students in certain regions of North America (Smith and Farah 2011). Only within the last few years has the evidence base grown to become more internationally representative (Castaldi et al. 2012; Franke et al. 2011; Partridge et al. 2012). Students, however, are still the focus of the majority of these studies. Curiosity about where, and among which other groups, cognitive enhancement occurs has spurred some interest in carrying out informal studies. One often cited example is a poll conducted by the scientific journal, *Nature* (Maher 2008). Based on responses of 1,400 respondents from 60 countries, the poll revealed that one in five respondents had used medications nonmedically to increase focus, concentration and memory. Another and more specific example of an unofficial, yet published, prevalence study is a survey of Cambridge University students conducted by the university's newspaper, *Varsity*. Of the 100 students surveyed, 1 in 10 admitted to using medications for cognitive enhancement (Lennard 2009). The results of a similar survey conducted by *Newsnight* and the *New Scientist* magazine were published on the BBCNews website (Watts 2011). Of the 761 respondents 38 % said they had taken a drug for cognitive enhancement. The vastly different results of the unofficial prevalence studies could be a reflection of actual variations in prevalence between regions and groups. However, the results cannot be compared or verified because the methods are not available for review nor have the publications undergone peer review.

Reporting and gathering of prevalence data on cognitive enhancement is creating what may be problematic interplay between the various forms of media and bioethics scholarship. Partridge et al. (2011) found that the media articles in their sample most often reported cognitive enhancement as being common or increasing in prevalence. The authors observed that the media often misinterpreted prevalence data. What is perhaps most concerning about this finding is that the misinterpretations of prevalence from media articles have appeared as references in scholarly papers supporting "a trend toward growing use of prescriptions stimulants by healthy individuals for the purpose of enhancing school or work performance" (Smith and Farah 2011 p.717). Informal studies of prevalence conducted by journals and newspapers have also been cited in academic circles as an indication of increasing or high prevalence. Despite a lack of demographic data of the sample, the results from the *Nature* poll have been used by scholars to support claims that cognitive enhancement is not only widespread but also in demand (Greely et al. 2008). The *Varsity* figures have also been cited in the academic literature as sources supporting increasing use of medications for cognitive enhancement

(Mohamed and Sahakian 2011). The uptake of media reports indicating increasing prevalence in bioethics discourse creates a situation where it is difficult to ascertain whether the impression of increasing prevalence originated in the media or the bioethics literature. Both discourses seem to be contributing to the inflation of the perceived high prevalence of cognitive enhancement among university students (Lucke et al. 2011). For now, these types of journalistic-empirical studies are giving credibility to unverified prevalence rates, while the academic empirical studies and their interpretation remain contentious.

Journalists Researching the Efficacy of Medications on Healthy Individuals

Another key element of media reports on cognitive enhancement is the evidence supporting the efficacy of purported cognitive enhancers on healthy individuals. References in the media to controlled trials of efficacy appear inconsistently. Consequently, readers may feel inadequately informed regarding the scientific basis of the benefits and risks mentioned in the report (Forlini and Racine 2012). Existing evidence from clinical trials does not currently support the use of prescription medications in healthy individuals for enhancement (Repantis et al. 2008, 2010a, b). Only a few studies have demonstrated that stimulants produce a modest benefit for lower-performing individuals (Ilieva et al. 2013). Yet, anecdotal reports of efficacy are pervasive in media reports (Schwarz 2012; Talbot 2009). In fact, a study of media coverage on the nonmedical use of methylphenidate in university students showed that the media reported the benefits of cognitive enhancement more often than the risks (Forlini and Racine 2009b). The concern remains that media reports emphasizing the benefits of cognitive enhancement and describing anecdotal efficacy would encourage the nonmedical use of prescription medications for enhancement purposes (Forlini and Racine 2012; Partridge et al. 2011). The bioethics literature has also been the target of criticism for over-enthusiasm about cognitive enhancement (e.g., Bostrom and Sandberg 2009; Greely et al. 2008) despite the lack of efficacy data to support the use of medications in healthy individuals stressed by some (Racine and Forlini 2009). In addition to prevalence, efficacy of medications has provided an element for both the media and those contributing to bioethics scholarship to speculate on. As a result, they both risk portraying the efficacy of purported enhancers in an enthusiastic light.

The gap in knowledge about efficacy has driven some journalists to seek a better, and often more personal, grasp on the effects of medications on healthy individuals. On the one hand, many journalists have approached individuals who do engage in cognitive enhancement to explain the effects they experienced. On the other hand, some journalists have opted to explore the subjective effects themselves. By self-experimenting, the journalist acts as both researcher and research subject in order to gain information about yet another aspect of cognitive enhancement whose evidence base is contentious. These journalists set the plan for what they will experiment with and when (researcher) but are also subjectively reporting the results of their informal study (research subject). The self-experimentation of

journalists, however, establishes a basis for anecdotal efficacy evidence that can be cited with the same deceptive authority similar to unofficial surveys.

There are several notable examples of the journalist-researcher. In one article, Hyland (2013) orders modafinil from a website upon hearing of a friend's positive experience using the medication to be more productive. Her article focused on how modafinil could help her cope with the fatigue caused by multiple sclerosis, a condition that is not part of modafinil's indicated uses. She clearly states that "if it worked, I'd take my anecdotal evidence of the drug's effects to both my neurologist and my GP" (Hyland 2013). Thus, this experiment was done without any type of medical supervision. After experiencing positive results, the author carried on using modafinil she ordered from the Internet until her neurologist was able to issue a legitimate prescription (following a refusal from her primary care physician and resistance from healthcare services).

The author of a 2012 feature in *Rolling Stone* Magazine also experimented with modafinil and other marketed nootropics available on the Internet (McMillen 2012). McMillen reported experiencing positive effects from modafinil and other substances he experimented with. This reporter also diligently documented the negative side effects that he experienced.

A third example comes from a BBCNews reporter. In contrast to Hyland and McMillen, Watts sought the supervision of a neurologist. The physician carried out cognitive testing to evaluate the reporter's performance while using modafinil on one day as compared to a placebo on another day. Though the results showed that Watts performed better using modafinil, when asked to guess which substance she had taken on which day, she was unable to identify the day she took modafinil (Watts 2011).

Similar to the trend reporting, articles based on journalist self-experimentation provide a how-to guide to would-be users of medications for cognitive enhancement. However, the first person narrative of self-experimentation reports contains some added incentives for would-be users. The means employed to obtain substances for experimentation are usually detailed and, most of all, successful. Both Hyland and McMillen demonstrated how easily one could procure medications online. Examples of how drastically the substances impacted the work and productivity of the journalist-researcher that tip the balance in favor of the positive effects might empower readers into following the self-experimentation of journalists. Consequently, these types of reports could undermine measures aimed at reducing the nonmedical use of medications, regardless of the real-world efficacy of cognitive enhancers.

There are two important and intimately linked ethical issues that arise specifically from reports based on self-experimentation. The first issue is the safety of experimenting with medications for unregulated purposes. The second is the legal aspects generally related to the nonmedical use of medications. Watts was supervised by a neurologist who verified that modafinil would pose no risk to the journalist. There were also medically trained staff nearby during the experiment (Watts 2011). However, according to Downie et al. the physician would be liable for any unforeseen harm that could have befallen the journalist during the cognitive enhancement experiment (Downie et al. 2010). McMillen's article does acknowledge the risk of taking the prescription medications and other nootropics with which

he experiments. A disclaimer at the end of the article warned that, "At no point should any of the products mentioned in this article be ingested without first consulting a health professional" (McMillen 2012). Hyland's article features no such disclaimer. This disclaimer is problematic on two fronts. Though it acknowledges risks, the disclaimer sends a contradictory message and sets a poor example for readers when the journalist had not taken that same precaution. The disclaimer seems to protect the author and publisher from liability more than the safety of the individual who may decide to follow the example of the journalist in trying medications or substances for enhancement purposes. Hyland and McMillen's experiments evoke legal aspects related to the purchase and possession of prescription medications without a prescription. Both these journalists purchased modafinil over the Internet. Aside from not being able to verify the authenticity of the medications they were receiving and ingesting, it is technically illegal for them to possess these drugs (Downie et al. 2010). Even if there is an acknowledgement that these drugs could be harmful and are obtained from illicit sources, there still seems to be tolerance for experimentation with suggested cognitive enhancers for journalistic endeavors in spite of national public health agencies attempting to curtail nonmedical uses of prescription drugs. Different frameworks that cut across disciplinary boundaries have been used to discuss cognitive enhancement (Outram 2012; Racine and Forlini 2010). Previous work showed that the media adhered largely to a framework that portrayed cognitive enhancement as a lifestyle choice (Forlini and Racine 2009b). However, since this work was published, some recent reports have adopted frameworks that reflect the ethical discussions on media prescription practices (Schwarz 2012) and investigate what the effects and benefits of purported cognitive-enhancing medications for healthy individuals might be (McMillen 2012).

Reports over Social Media: The Public Becomes the Journalist

In the previous sections of this chapter, we mentioned two sources of information on cognitive enhancement: academic research and the popular media. In the context of cognitive enhancement, social media warrant attention as another source of public information for those who engage with the range of social media available, many of whom are young people. Social media include networking sites such as Facebook and Twitter, and personal blogs. With social media, the research and writing is not only being done by professionals (i.e., researchers or journalists) but also by anyone with an opinion or an experience to share. In this way, members of the public are consuming and *creating* messages about cognitive enhancement. Social media harness the power of anecdotal reports just as the traditional media do, and academic papers have been inclined to do, in the context of cognitive enhancement (Sahakian and Morein-Zamir 2007). The unique power of social media is that the sources of the anecdotes are friends, acquaintances, and others that one can *choose* to follow.

There is a cacophony of chatter about cognitive enhancement over social media. Internet searches can reveal declarations of need for cognitive enhancers, requests for sources to obtain cognitive enhancers illicitly, and discussion of the effects of medications. There are blogs explaining the effects of various substances including

the legal implications (Anonymous 2012) and YouTube videos conducting informal efficacy trials ("Smart Drugs and Memory Enhancers," 2012). Talk of cognitive enhancement using prescription medications over social media is largely uncharted territory for academic research. Hanson et al. conducted a highly relevant study that monitored tweets containing the term "Adderall" and found 213,633 tweets from 132,099 unique user accounts over 6 months in the USA (Hanson et al. 2013). The authors reported that:

> The number of Adderall tweets peaked during traditional college and university final exam periods. Rates of Adderall tweeters were highest among college and university clusters in the northeast and south regions of the United States. 27,473 (12.9 %) mentioned an alternative motive (e.g., study aid) in the same tweet" (Hanson et al. 2013).

Further examination of the cognitive enhancement content of social media would yield insightful information on how cognitive enhancement is being portrayed in informal and often very short messages. Hanson et al. conclude that the content of social media can contribute to the formation of normative behaviors regarding the use of stimulants and other medications for enhancement purposes. A previous qualitative study of different stakeholder groups similarly demonstrated how perceived acceptability or necessity of a practice like cognitive enhancement can have an impact upon individual behaviors (Forlini and Racine 2009a). Information over social media is disseminated at an astonishingly rapid rate. With the potential to "go viral," the impact of blogs, tweets, and status updates on normative behaviors can be more influential than traditional forms of media.

Bioethics Literature and the Media: Sharing the Responsibility to Discuss and Reflect on Cognitive Enhancement

The media have contributed to various facets of the cognitive enhancement debate and bioethics scholarship. The subject of cognitive enhancement has permeated popular culture, sparking various representations of what it means to enhance cognition and what the consequences may be (McKenna 2011a, b). Some of the media's interest for cognitive enhancement might be explained by the multifaceted nature of the phenomenon. These types of contributions have broadened the scope of media presence in the cognitive enhancement debate. However, distinguishing the anecdotal evidence from scientific evidence in media reports on cognitive enhancement may not always be obvious for audiences. The experiences of reputable journalists and social media contacts can be more accessible than academic research. Furthermore, testimonials from these sources carry weight with readers and followers. Pop culture representations have also been shown to reinforce stereotypes of cognitive enhancement "as an admirable attempt to succeed in a troubled system" (McKenna 2011a p. 92). In a joint guide for journalists, the UK Drug Policy Commission and the Society for Editors acknowledge the policy and social implications of media reports on illicit drug use. The guide cautions against relying on anecdotal or uncertain evidence about substances and employing language that reinforces drug-related stigma (Society of

Editors and UK Drug Policy Commission 2012). Piercing through the dissemination of anecdotal evidence and reinforcement of stereotypes in popular culture is a complicated task for researchers who are trying to communicate nuanced messages about cognitive enhancement, especially regarding its prevalence and efficacy. Journalists face an equal challenge in discussing aspects of a socially relevant phenomenon where evidence is absent or disputed.

In seeking and reporting anecdotal information, journalists balance their responsibility to convey information about a phenomenon against the potential to encourage the nonmedical use of medications for cognitive enhancement. Stakeholders have been shown to value the information in media reports while being concerned with media coverage that encourages further use (Forlini and Racine 2012). Encouragement, whether intentional or collateral, might come through demonstrating the ease with which medications can be obtained without a prescription, describing positive or life-changing effects of enhancers, and describing perceptions of acceptability of cognitive enhancement among certain groups. Concerns about media reporting of drugs and drug addiction prompted the Australian Press Council to release practice guidelines (Australian Press Council 2001). In essence, these guidelines urge journalists to guard against reporting of details that would facilitate or encourage self-experimentation relating to illicit drug use and abuse. Given the circumstances of how prescription medications for cognitive enhancement are obtained, the potential negative effects and lack of medical supervision, following the guidelines of the Australian Press Council, would be a relevant precaution for journalists to take when reporting on cognitive enhancement, particularly when it involves illegal activity.

Various forms of media are often blamed for misinterpreting, misrepresenting, or hyping scientific evidence which, ultimately, skews public understanding (Seale 2003). The goal of this chapter was not to criticize media reports on cognitive enhancement per se but rather to characterize the role popular media have played in the debate (including its academic counterpart) and the types of information it has contributed. Moreover, we sought to raise awareness of the contribution of academic bioethics literature in subscribing to anecdotal evidence and elements of hype. In a recent report, the Nuffield Council on Bioethics acknowledged the contribution of researchers and media alike in the "spiral of hype" for novel neurotechnologies (Nuffield Council on Bioethics 2013 p. 17). The Council recommended that "Researchers, press officers and journalists . . . reflect on how their representations might contribute to hype, and exercise caution when describing the possible applications of a technology" (Nuffield Council on Bioethics 2013 p. 17). The very term ("cognitive enhancement") used in bioethics discourse has been critiqued for the assumptions and expectations for benefit that it creates (Outram 2012; Racine and Forlini 2009). In this sense, the media cannot be faulted for following the cues of bioethicists. Responsibility for messages about cognitive enhancement is shared between the media and those contributing to bioethics scholarship. Many groups have suggested ways to improve science communication (Bubela et al. 2009; Illes et al. 2010), and recent projects have ventured into more interventional approaches to match scientific expertise with journalistic endeavors (Callaway 2013). Improving scientific communication is not only about improving the scientific

literacy of members of the media, but also making researchers more media-literate. In addition, others have recommended that bioethics scholarship adopts more explicitly methodological approaches (e.g., acknowledging assumptions, validating assumptions, adopting broader frameworks) to prevent hasty leaps of faith (Racine et al. under review). An outstanding question, however, remains whether and how social media will be influenced by changes in scholarly papers or media reports. In Box 1, we make some suggestions regarding avenues for future research that could help understand and respond to media messages on cognitive enhancement in addition to identifying the aspects of cognitive enhancement research which are vulnerable to misinterpretation.

Box 1: Recommendations for Academic Research Examining the Content and Impact of Media Reports on Cognitive Enhancement

Implications of Conventional and Social Media for Academic Research

- Measurement of the impact of media coverage of enhancement controversy on academic scholarship
- Demonstration of the impact of expectations of public visibility of bioethics scholarship on attitudes defended by bioethics scholars in academic literature and in the media
- Recommendations for proper use of levels of evidence in the media and academic scholarship
- Characterization of the impact of various pressures for "translation" of academic research on media portrayal of cognitive enhancement
- Understanding the relationship between journalists and academic researchers

Content and Impact of Conventional and Social Media

- Further characterization of the content of international conventional media as well as social media
- Understanding patterns of social media use for disseminating messages on cognitive enhancement
- Comparison of conventional versus social media on attitudes and behaviors in specific stakeholder groups
- Understanding diverging practices for media content on illicit drugs versus nonmedical use of prescription drugs

Conclusion

Media reports and academic publications both strive to collect and disseminate information. However, they differ with respect to their audiences, methods, and

formats, which, in turn, relate to the distinction between the tasks of journalists and those of researchers. It is important to keep these distinct roles in mind when studying media portrayals of phenomena like cognitive enhancement that beg both scientific as well as social and ethical questions. Collaborative projects between researchers and journalists are one way of improving communication about evidence, practices, and attitudes related to cognitive enhancement (Lucke, Partridge, & Hall 2012). However, an essential part of studying cognitive enhancement from ethical and journalistic perspectives is an awareness of the shared commitment and responsibility in accurately representing evidence and practices.

Neuroethics Beyond Traditional Media

94

Chiara Saviane

Contents

Abstract

Brain science is vital to help us understand how the brain works and identify brain disease treatments. Fast technological advances are opening doors to clinical and nonclinical applications which may affect our health as well as different aspects of our society, from education to business and criminal justice. The scope, benefits, and risks of new technologies and therapies are still uncertain, but they raise crucial ethical, social, and legal issues which involve people from all walks of life. Citizens need to acquire the competences to make informed choices and contribute to decision-making processes which may be critical for their life and the society they want to live in. To this aim, several activities have been promoted over the last decade at the European level, thanks to key players such as the European Commission and the European Dana Alliance for the Brain.

This chapter describes in detail some major European initiatives which have used different approaches beyond traditional media to raise public awareness and

engagement in neuroscience and neuroethics, providing sound information, fostering multidisciplinary debates and participation to policy-making processes. These include European projects, such as Brains in Dialogue, Meeting of Minds and Decide, and many activities promoted by the European Dana Alliance for the Brain. Some impediments still exist for a true dialogue and a real involvement of citizens in decision-making processes; however, some successful approaches, ranging from public events to social media, have been identified and could be developed and investigated further.

Neuroscience and Society

Over the recent years, philosophers, social scientists, and some neuroscientists have started to investigate the ethical, legal, and social implications of brain science. However, these issues concern so many aspects of our life and our society that, with time, the urge of a multidisciplinary approach as well as the importance of public engagement in such discussions have become clear.

Actually the type and quality of the debate on neuroethics differs from country to country (Illes et al. 2005). The United States, followed by Canada, has been the center of neuroethics activity in the twenty-first century. Many events have been held to define the field and also to engage the public, fostering a deeper understanding of the issues as well as a lively participation in the dialogue already from the beginning. In Europe, the approach to public engagement is still changing and not without some difficulties. The Bodmer report and the following establishment of a Committee on the Public Understanding of Science in 1986 marked the beginning of a series of educational activities in the United Kingdom, and then in Europe, to bridge science and society. However, the need of a shift from a top-down approach to a two-way communication in the relationship between science and society became evident only at the beginning of the twenty-first century. In the United Kingdom, a report published in 2000 by the House of Lords Science and Technology Select Committee entitled "Science and society" described the results of a national survey highlighting a "new mood for dialogue" due to the lack of trust in science among British Citizens (http://www.publications.parliament.uk/pa/ld199900/ldselect/ldsctech/38/3801.htm). The report provided different recommendations on how to put this in practice at the national level, focusing on issues that are still crucial today such as risk and uncertainty communication, science education in schools, and the relationship between science and media. The following year a Eurobarometer Survey conducted in fifteen Member States ("Europeans, science and technology," 2001) reported a mixed attitude among European citizens ranging from confidence and high expectations in science to a complete lack of interest or trust accompanied by a concern about the rapid pace of advancement. Thus, in December 2001, the European Commission agreed a "Science and Society Action Plan" with 38 actions for the establishment of a "new partnership" between science and society ("Science and Society Action Plan," 2002). It was clear that, in order to meet the needs of European citizens and regain their support, it

was necessary to foster public awareness, providing understandable and sound information, but it was also important to encourage a true engagement, establishing a dialogue with citizens and giving them the opportunity to express their views in the appropriate bodies.

Since then, the European Commission has supported several initiatives to foster a dialogue between science and society and bring science policy closer to citizens. Some of these were focused on neuroscience like the Brains in Dialogue and the Meeting of Minds projects. Starting from these experiences, this chapter presents some examples of nontraditional approaches and media used over the last decade in Europe to foster public awareness and engagement in neuroscience and neuroethics, in settings that run from real to virtual.

The Brains in Dialogue Project: Brain Science at the Service of European Citizens

The Brains in Dialogue project (BID) was a three-year project supported by the European Commission under the Seventh Framework Programme and coordinated by the International School for Advanced Studies (SISSA) in Trieste, Italy. Focusing on brain imaging, brain devices, and predictive medicine in brain science, the project aimed at fostering public engagement and a multidisciplinary dialogue between key stakeholders, including scientists, clinicians, philosophers, social scientists, lawyers, economists, journalists, science communicators, patients, service users, lay public, etc. With a scientific and communicative mission, BID used different approaches to communicate the state of the art, discuss the expectations, benefits and risks of new technologies and therapies in neuroscience, build constructive discussions on the ethical, legal, and social issues, and test novel "dialogue products" which integrate lay and scientific knowledge. In particular, between 2008 and 2011, BID organized three interdisciplinary workshops and several public events, managed the website *neuromedia corner* (www.neuromedia.eu) and a press office active at a European level (Ramani and Saviane 2010).

The events represented the core of the project, where different stakeholders – including lay citizens – had the opportunity to meet and address specific issues from different perspectives. The workshops were organized as closed meetings with a limited number of participants and ample time for interactions in order to establish an informal environment and facilitate a true dialogue. Speakers and participants from different countries and fields of research were chosen in order to create an interdisciplinary and international group which could also take into account cultural differences. In particular, a great effort was dedicated to the involvement of patients and service users as speakers or participants, in order to bring their views – often missing – in the debate. Science communicators and journalists were also involved to help the discussion as well as to analyze and stress the difficult relationship between scientists and media and the crucial role of media in shaping public opinion.

The workshops involved between 40 and 70 participants including scientists, clinicians, patients, sociologists, lawyers, philosophers, economists, service users, delegates of the European Commission, science communicators, and other experts from up to 25 European and extra-European countries. The meetings comprised sessions of nontechnical talks and facilitated discussions aimed at providing background information on the different aspects of the topic (scientific, clinical, ethical, legal, economic, etc.) and finding a common language. A final session was aimed at testing new dialogue formats, spanning from group activities to discussion games, in order to achieve a lively debate among all participants and encourage them to change perspective for a while. The discussion was always open to the general public with a round table or Café Scientifique organized in collaboration with the local institutes.

In order to reach experts and citizens from several countries, the workshops and public events were organized in different locations across Europe. The first BID workshop – "Brains in dialogue on brain imaging" – took place in Cambridge, UK, and focused on the current and potential applications of brain imaging in psychiatry. The meeting ended with the *Café Scientifique* "Can we read minds?" which was part of the Cambridge Science Festival and the Brain Awareness Week and focused on the scope and limits of brain imaging technologies for mind-reading and their potential use for nonclinical applications such as lie-detection. The second workshop – "Brains in dialogue on genetic testing" – took place in Trieste, Italy, and addressed the state of the art of predictive genetic testing for neurodegenerative diseases. The discussion was opened to the general public with the round table "Health and DNA: my life, my genes". The last workshop – "Brains in dialogue on deep brain stimulation" – was held in Warsaw, Poland. The meeting focused on the potentials and limitations of deep brain stimulation with great attention to the patients' perspective and the role of media. It ended with the *Café Scientifique* "Brain, machine and something in between" which took place as part of the Warsaw Science Festival and addressed the state of the art and the ethical implications of deep brain stimulation and brain machine interfaces.

Among other initiatives, BID also organized the round table "When the final hours come: End of life care, ethics, costs, and the role of the media" as part of the Euroscience Open Forum (ESOF) 2010. It involved clinicians, scientists, and philosophers as well as journalists coming from some of the most important newspapers and magazines in Europe.

The challenges for an appropriate and effective communication to the general public represented a regular topic of discussion throughout the project. The debate among researchers and journalists on the different responsibilities still seems to be alive. Some academics do not see the importance of improving their communication skills or understanding the media logic for an appropriate public communication and a fruitful interdisciplinary dialogue. However, most of BID participants agreed on the need to train scientists in science communication, an old resolution which has not been put into practice yet and is often still a matter of debate. In this regard, BID organized, in collaboration with the European Science

Communication Network (ESConet), a training workshop on neuroscience communication for young researchers from different disciplines interested in the social, ethical, and legal implications of neuroscience.

The discussions started live during the meetings continued virtually on the online hub of BID, the *neuromedia corner*, and more broadly on the web to reach different stakeholders, through the publications of video interviews, interdisciplinary special issues, and articles for national and international newspapers and magazines.

The BID team wrote press releases as well as lay and scientific articles for national newspapers and international journals to reach the general public and academics from different fields. Moreover, the involvement of European science journalists in the workshops generated an international coverage through press articles, radio, and even TV programs. BID edited two special issues on open-access scientific journals with mini-reviews, perspectives, and opinion papers from some of the workshops' participants offering different perspectives: the Research Topic entitled "Emerging issues in brain imaging: a multidisciplinary dialogue" (http://www.frontiersin.org/HumanNeuroscience/researchtopics/emerging_issues_in_brain_imagi/58), published on *Frontiers in Human Neuroscience*, and the Research Topic "The development of deep brain stimulation for neurological and psychiatric disorders: clinical, societal and ethical issues" (http://www.frontiersin.org/IntegrativeNeuroscience/researchtopics/the_development_of_deep_brain_/127), published on *Frontiers in Integrative Neuroscience*. These works represented important opportunities to raise awareness in the neuroscience community about the social, ethical, legal implications of these technologies as well as the patients' perspective and the crucial role of science communication.

The material collected throughout the project was uploaded, and is still available on the website *neuromedia corner* (www.neuromedia.eu), a portal where experts and lay citizens can find original news, scientific content, video interviews, research centers, events, and useful links. The website had a journal-like home page, with news and pictures regularly updated. It contained all outcome material related to BID activities and also provided media operators with useful and understandable news and information. A special section named Viewpoints focused on the social implication of BID scientific areas through a collection of peer-reviewed papers and news items from international scientific and lay journals. In order to increase the visibility of the project and the website and foster the discussion, a Facebook page was also created under the name *neuromediacorner* with links to the project website or to interesting news, pictures of the BID events, and comments. About ten video interviews were recorded during each workshop with key messages from different stakeholders, from academics to clinicians and patients. After editing and approval by the interviewees, these were uploaded on *neuromedia corner* and the *neuromediacorner*'s channel of YouTube (http://www.youtube.com/user/neuromediacorner) to give an overview of the different aspects of the topics addressed. The publication on YouTube made the interviews more accessible for lay surfers and increased their visibility, up to more than 2,000 views per interview, through referral from related videos and specific searches.

On July 2011 BID final conference – "Dialogue to dialogue" – took place in Brussels, Belgium, where three and a half years of initiatives, workshops, publications about neuroscience and its impact on society were presented in a public conference. Despite its success and the enthusiasm of most participants, the BID project revealed that some stakeholders – mainly senior scientists – are still not sufficiently interested or ready to engage in a multidisciplinary dialogue or to open the debate to the general public (Ramani and Saviane 2010). Many of them are so busy and focused on their field of research that they do not see much added value in a better understanding of the real impact of their results on individual's life and society. It is clear that a dialogue between neuroscience and society is an achievement as important as difficult to put into practice and main efforts should be directed toward the younger generations. More experiences like BID, with real opportunities of interdisciplinary and uncommon exchanges and interactions, are still needed. Actually BID was of inspiration for the new European project NERRI – Neuro-Enhancement Responsible Research and Innovation – which involves 18 partners from 11 European countries (www.nerri.eu). NERRI aims to contribute to the introduction of responsible research and innovation in neuroenhancement in the European Research Area and to the shaping of a normative framework underpinning the regulation of neuroenhancement technologies. These will be achieved through mobilization and mutual learning activities engaging scientists, policy-makers, industry, civil society groups, and the wider public.

The Meeting of Minds Project: European Citizens' Deliberation on Brain Science

The Meeting of Minds (http://www.kbs-frb.be/otheractivity.aspx?id=193934&langtype=1033) was a two-year pilot project aimed at involving European citizens in the discussion and assessment of brain science in order to give relevant inputs into European policy-making and foster a wider public debate on this topic. Funded by the European Commission under the Sixth Framework Programme a nd coordinated by the King Baudouin Foundation (Belgium), the project involved 12 institutions from 9 European countries (Belgium, Denmark, France, Germany, Greece, Hungary, Italy, the Netherlands, and the United Kingdom) and a panel of 126 European citizens.

The project was inspired by the increase in participatory technology assessment and foresight in various European national contexts. These approaches had been previously used to discuss scientific and technological issues with experts, policy-makers, citizens, and relevant stakeholders in order to provide policy advice, foster public debate and mutual learning among the different stakeholders. The Meeting of Minds was thought as an attempt to bring this procedure to a European cross-national level, addressing a topic of growing impact for society. The methodology was built on the expertise of the consortium members, which included technology assessment bodies, science museums, academic institutions, and public

foundations, according to a set of criteria which required – among others – an innovative character, a European dimension, a relevance for the public policy, a central role for citizens in the deliberation process, transparency, and accountability.

The project consisted of three National and two European meetings held between 2005 and 2006. It involved 9 national panels of 14 citizens selected in order to guarantee gender balance and a broad range of age and educational background. An advisory board with neuroscientists, psychiatrists, and other stakeholders in the field of brain science was established in each country as guarantee of the quality of the content and the method of the project. The first Introductory National Meetings were held in April–May 2005 with the aim of gathering the panelists and preparing them for the whole process. Six challenging case studies, described in an information brochure, were used to introduce different topics of brain science and the related social and ethical issues: from depression to Alzheimer's disease, from brain imaging to deep brain stimulation, from medicalization to brain enhancement. The opinions, ideas, and concerns raised during the National Meetings were shared during the first European Citizens' Convention in order to get a European perspective. On this occasion, through international group discussions and voting procedures, the panelists identified six broad themes (Regulation and Control; Normalcy vs. Diversity; Public Information and Communication; Pressure from Economic Interests; Equal Access to Treatment; Freedom of Choice) and related sets of questions for the following steps to be taken. Two National Citizens' Assessment Meetings were organized in the following months to give citizens the opportunity to discuss in further depth the themes selected together with scientists, policy-makers, and other stakeholders. The national panels identified key issues within each theme and drafted some recommendations to share in the second, and final, European Citizens' Convention, held in January 2006. On this occasion, the citizens used different dialogue formats – from plenary sessions to carousel sessions and European Cafés – to review the issues, identify the most relevant two for each theme, and then formulate recommendations. At the end of the Convention, a final European Citizens' Assessment report with 37 recommendations on the social, ethical, and legal implications of brain science was presented during a public ceremony at the European Parliament to key policy-makers, scientists, and other stakeholders.

In order to promote the project results and guarantee public visibility of the initiative, the media and the general public were involved at crucial stages of the process at the national and European level. Two European Stakeholders Meetings were also organized during the project to promote the project and create synergies with other initiatives at the European level. Moreover, since January 2006, the different partner organizations, as well as some of the panelists, have been involved in dissemination initiatives at a national and international level. These include presentations in national parliaments, public events, and a broad range of scientific conferences related to science, ethics, and participatory approaches in science and technology.

The Meeting of Minds project still represents a unique example on how to develop and implement a participatory technology assessment process at the European level. As stated in the external evaluation report (Goldschmidt and Renn 2006) “The Project Meeting of Minds accomplished all envisioned objectives – the content related objectives with great success, the procedural objectives with satisfactory success.” In fact, despite some practical problems related to the European Conventions, the project managed to engage citizens in a multi-lingual and multicultural context and allowed them to feel and act as European citizens, providing policy advices in a field of great impact for the individuals and the society. The experiences collected are of great value for the development of this type of participatory procedure and have also highlighted the importance to further engage the citizens in the debate on neuroscience. Unfortunately, the real impact of the results and recommendations at the policy level is unclear, or minor, despite the hopes of the people involved and the efforts made by the organizations. Certainly, too many factors are involved in policy development, especially at the European level.

Discussion Games and Debate Formats

The need to find new approaches to engage the public in science has led to the development of debate formats and discussion games aimed at different targets and different settings.

A successful example is the discussion game PlayDecide (www.playdecide.eu/) created by the European project Decide – Deliberative Citizens’ Debate – in order to understand the potential role of science centers in the democratization of science. The project, started in 2004 and supported by the Scientific Advice and Governance Unit of the European Commission, had three main goals: to raise awareness of the potential of participatory and deliberative consultations, to collect data from debates on controversial issues in science, and to provide a downloadable kit to conduct debates and discussions in science centers (Bandelli and Konijn 2011). It involved museums and science centers, advocacy group associations, and nongovernmental organizations.

PlayDecide is a card game focused on controversial topics in science, including neuroscience. It was inspired by the card game Democs, developed by the New Economics Foundation to help people discuss about politics using visual thinking and participatory methodologies. The game uses three sets of cards (Info, Issue, and Story cards) that provide information and highlight controversial issues to set up discussion groups of up to eight people. The instructions and material needed are available online and downloadable in different languages. After a first briefing phase, the group addresses specific issues to see whether the participants share common views. Finally, the group has to discuss and vote some predefined policies on the topic or even suggest their own. The results can then be uploaded on the website for a comparison across countries. Although a playful activity, PlayDecide is a “serious game” and the clarification of the aim of the discussion is a critical step for its success.

Over the years, users of PlayDecide have started to develop new kits or adapt them to different targets and situations, such as students in the classroom or specific local contexts (Bandelli and Konijn 2011). The consortium realized that the co-development of kits by the users was the added value of the tool. They decided to encourage this by allowing the use of a more relaxed license as well as by providing micro-grants and training for people interested in employing PlayDecide to foster debates and participation.

A kit on "Brain enhancement" is available in 18 languages. Through the different sets of cards, participants learn something and discuss about consciousness, drug resistance, deep brain stimulation, memory-enhancing drugs, and more. More kits could be developed on specific issues of neuroscience and neuroethics and thus become a useful tool for public engagement on those issues. For example, a draft on neuromarketing was prepared by the students of the Master's Course in Science Communication at the International School for Advanced Studies (SISSA) in Trieste, Italy.

A similar initiative which is worth mentioning is the project Citizen Science, ran between 2004 and 2006 and supported by the Wellcome Trust. Citizen Science was set up by the At-Bristol Education team and by the University of Bristol, involving teachers and scientists. It led to the development of different debate formats and settings inspired by games, role play, television chat shows, etc. to engage students in the debate on scientific controversial issues, such as genetic testing, nanotechnology, in vitro fertilization, and alcohol and drug consumption. About 30 events per year were organized in the UK as well as training courses for teachers and science museum staff. The most successful formats are still available online (http://www.at-bristol.co.uk/cz/teachers/Default.htm) and could be of inspiration for the discussion on neuroethical issues.

The BID project, for example, has developed, for one of the workshops, a discussion game built on the model of the "discussion continuum." Divided into groups of eight to nine people, the participants, including experts and patients, were invited to debate about a list of statements covering some critical aspects of deep brain stimulation. Despite the initial skepticism, most of the attendees enjoyed this format of discussion which was a great opportunity for all to express their thoughts and points of view.

The European Dana Alliance for the Brain and the Dana Foundation Website

The European Dana Alliance for the Brain (EDAB: http://www.dana.org/danalliances/edab) plays a crucial role in Europe in fostering public awareness on brain research and its impact on society. Launched in 1997 and modeled on the US-based Dana Alliance for the Brain Initiatives (DABI), EDAB is a nonprofit organization involving more than 200 brain scientists from 29 countries. Entirely supported by the Dana Foundation, EDAB coordinates the Brain Awareness Week in Europe and collaborates with universities, schools, and other organizations to raise public awareness and engagement in brain science.

Started nationwide in 1996 by DABI, the Brain Awareness Week is now a global celebration of the brain for people of all ages (http://dana.org/brainweek/). Every year in March, for a whole week, hundreds of research institutes, schools, and health organizations worldwide contribute to the organization of a rich and diverse program including debates, lectures, experimental workshops, exhibitions, and more. Since its establishment, more than 2,800 partners in 82 countries have participated in the campaign. More and more of these events focus on – or at least touch – the social, ethical, and legal implications of brain science.

Actually, EDAB organizes outreach events on neuroscience and neuroethics throughout the year. A strategic location is the Science Museum's Dana Centre, an adult-only venue in Central London built on purpose to foster public engagement in science in a lively and informal atmosphere through debates, performances, and multimedia facilities. Since the Centre is a collaboration between EDAB, the British Science Association, and the Science Museum, the events cover the whole range of science issues but a focus on neuroscience and neuroethics is predictable since it hosts one of EDAB's offices.

EDAB takes also part in international conferences like the EuroScience Open Forum (ESOF) or the meeting of the Federation of European Neuroscience Societies (FENS). An example is the last William Safire Seminar on Neuroethics held in Barcelona during FENS 2012 and organized in collaboration with the International Neuroethics Society. The seminar entitled "Invading the Brain: What Are the Ethical Issues on Invasive Treatments for Brain Disorders?" touched on the benefits, limits, and ethical implications of new techniques like deep brain stimulation, cell transplantation, and gene therapy. EDAB was also among the eighteen societies contributing to the BNA 2013: Festival of Neuroscience (http://www.bna2013.com/), a unique event organized in occasion of the annual meeting of the British Neuroscience Association and one of the most exciting events in the 2013 neuroscience calendar. Parallel to an intense scientific program that included public and plenary lectures, workshops, symposia, and poster sessions, a rich public engagement program with film screenings, theatrical events, art installations, and a hands-on Street Fair ran to allow the general public to interact with scientists as well as carers, patients, funders, and policy-makers and thus look at neuroscience from different perspectives. In collaboration with the International Neuroethics Society, EDAB was part of a session on "Public Awareness and Societal Impacts" with the workshop "Drugs and Society: The neuroethics of enhancing or erasing memories" focused on the state of the art, benefits, and risks of cognitive-enhancing drugs.

Through the Dana Foundation website (http://www.dana.org), EDAB also provides a wide perspective on the issues related to brain science and its ethical and social implications and offers a connection with a community active worldwide in these fields. EDAB offers a wide range of publications in different European languages, including reports, informative booklets for patients, carers and professionals, and resources for teachers and secondary school students. In particular, the Dana Foundation website includes a full section on neuroethics with original articles, links to news from external sources, information and coverage of events that range from the International Neuroethics Society Annual Meeting in the USA

to the Neuro-Ethics Film Festival in Edinburgh (Label of the 2012 Biomedical Ethics Film Festival). These topics are addressed with a dynamic and interactive approach also through the *Dana Foundation Blog* – which covers news and views on neuroscience, neuroethics, and neuroeducation – as well as on Twitter. The Brain Awareness Week can also be found on Facebook where it has a dedicated page that gives access to an International Calendar and a very useful set of resources including event ideas, planning tips, media and promotional strategies, and educational tools.

Conclusion and Future Directions

Brain science may play a crucial role in different spheres of our life. Not only for our health and access to treatments, but also because of the potential applications in different sectors of society such as education, business, politics, and criminal justice. It is more and more crucial for individuals to acquire the competences to make informed choices and contribute to decision-making processes on issues that may be critical for their life and the society they want to live in.

The debate on neuroethics involves many and different stakeholders and great effort still has to be made to find a common language to tackle these issues. In Europe, as emerged from the BID project, some stakeholders are not even interested in starting a dialogue. However, the experiences described in this chapter show that several initiatives created to raise public awareness and engagement on these issues have grown over the last few years, thanks to the support of key players such as the European Commission and the European Dana Alliance for the Brain.

Several approaches for raising public awareness and engagement beyond traditional media have been proven effective also for neuroscience and neuroethics and could definitely be explored further. From real to virtual, these range from the organization of public events to the use of the web and social media.

Different formats and settings for public events have developed over the years to achieve specific objectives and targets and represent important opportunities to learn and debate also about brain science and its impact on society. Science Festivals are an example among the different public engagement activities not connected to policy outcomes which have rapidly expanded worldwide over the recent years. They combine activities aimed at raising public awareness with others focused on fostering public engagement. A recent study investigated the interests, motivations, and benefits of people attending Science Festivals (Jensen and Buckley 2012). According to this, citizens value, in particular, the possibility of interacting with scientists and the variety of engagement offered for children, adults, and families and report an increased interest and curiosity in new fields of research. More and more often, some of the activities focus on neuroscience and neuroethics. The BID project took part in both Cambridge and Warsaw Science Festival with informal and multidisciplinary events on new applications of neuroscience. Both events turned into lively debates on the ethical and social implications of these technologies involving experts, citizens, and university

students, in particular. The BNA: Festival of Neuroscience took place in London in spring 2013 involving almost 2,000 delegates and more than 5,000 members of the general public (http://www.bna.org.uk/).

Similar opportunities for informal debates are offered on a regular basis by *Café Scientifiques* or Science Cafés (http://www.cafescientifique.org) which represent a forum for discussion in informal venues such as bars, cafés, and bookshops. These events have recently spread worldwide to more than two-hundred (http://www.cafescientifique.org/attachments/article/263/conferencereport.pdf, 2007) and usually address different science topics each time. However, there have also been examples of *Café Scientifiques* focused on neuroscience in Trieste (Italy), in Cardiff (UK), and in Montreal (Canada) as well as on neuroethics in Vancouver (Canada).

Science centers and museums have also become important venues for public awareness and engagement on crucial science and society issues such as climate change, stem cells, or gender gap (Bandelli and Konijn 2011). The Dana Centre is not the only example in Europe of a purpose-built facility to create dialogue opportunities on science, technology, and culture. Science centers and museums are also trying to become key players in the process of participation in the governance of science. The project PlayDecide was developed exactly with this aim and provides a valuable and adaptable tool that could be used further to discuss different issues in neuroethics. It also allows citizens to approach the process of policy-making before they can really play a role in it as the Meeting of Minds project showed that a real involvement in this process is, at present, difficult to achieve, especially at the European level.

The web and social media also represent key tools that should be mobilized further to foster public awareness and engagement on neuroscience and neuroethics. However, there is a central issue related to quality assessment of the information provided and credibility of sources, especially with regard to blogs and social networks. The connection to an established organization, magazine, or research institute may provide a sort of guarantee in this respect. This is the case for inputs by the Dana Foundation and the International Neuroethics Society or for blogs on these topics sponsored by *Nature* (http://blogs.nature.com/actionpotential), *Scientific American* (http://blogs.scientificamerican.com/bering-in-mind/) and *The Guardian* (http://www.guardian.co.uk/science/neurophilosophy). Several institutes in the United States also manage blogs that are often connected to a Facebook page or a Twitter account. Examples include *The neuroethics Blog* (http://www.theneuroethicsblog.com/) by the Center for Ethics at Emory University or *Mind the Gap* by the Center for Neuroscience and Society of the University of Pennsylvania (http://pennmindsthegap.wordpress.com/). Fewer examples can be found in Europe also because the search was limited to initiatives in English. The *neuromedia corner* represented an original attempt to provide sound information and foster the discussion on specific topics of neuroscience. It offered a lively website and a promising presence on Facebook and YouTube which, unfortunately, could not be explored and developed further due to the limited duration of the project. *The Practical Ethics Blog*

(http://blog.practicalethics.ox.ac.uk/) by the University of Oxford is the main example of blog at an institutional level, but some popular single-author blogs also exist.

The initiatives discussed in this chapter clearly represent a limited selection of major projects and key players at the European level. Many other relevant initiatives probably exist at a national level but are difficult to identify because of the language barrier.

The effects of activities of this kind emerge in a recent Eurobarometer Survey that suggests a "new era" in the relations between science and society ("Europeans and Biotechnology in 2010," 2010; Gaskell et al. 2011). According to this survey, European citizens show less criticism and more enthusiasm for new technologies even though they expect to see appropriate regulation for their use and ask for public involvement when social and ethical values are at risk. They also show general optimism for brain and cognitive enhancement research and even an approval of research on human enhancement, if kept under control. The survey investigated also the different influences that shape the relationship between science and ethics showing a complex pattern and a variability across countries which may hamper the definition of regulations at the European level and a true involvement of citizens in the process of policy-making. The Eurobarometer looked, in particular, at the influence of religion and education and identified different clusters of countries depending on the public's position on two crucial issues: whether science should prevail over science or vice versa and the "distributional fairness," i.e., whether the research may "benefit some people but put others at risk." These are crucial issues for neuroethics too and need to be addressed.

An excellent opportunity will be the "Year of the Brain" in 2014, a project promoted by the European Brain Council with "the ultimate goal to change and improve the way people think about the brain" (http://www.europeanbraincouncil.org/projects/eyob/). It includes the development of an interactive road show, school, and university program, a comprehensive website with features and articles for all forms of media, from TV to social networks. The project has already received enthusiastic support within Europe but has also generated interest outside the continent. Thus, the "Year of the Brain" in Europe 2014 has evolved into a three-year campaign called "The Age of the Brain", including the "Year of the Brain" in North America 2015 and the "Year of the Brain" in the Asia Pacific 2016. This will be a unique opportunity worldwide to foster awareness and engagement on brain science and the impact it may have on individuals' life and society. Hopefully, it will also be a starting point for more initiatives at the political and community level.

Traumatic Brain Injury and the Use of Documentary Narrative Media to Redress Social Stigma

95

Timothy Mark Krahn

Contents

Abstract

This chapter takes as its focus the topic of traumatic brain injury (TBI) from the perspective of "Public and Cultural Neuroethics," showing that there are deeply entrenched social and cultural barriers implicated in the trauma and injury commonly experienced by TBI survivors. The first section ("Traumatic Brain Injury (TBI) and the Situational Context for Survivors") details some basic facts about TBI and the situational context for this patient population. The second section ("Mistaken or Misattributed Beliefs About TBI") explains some of the prevalent societal misperceptions of persons living with TBIs, especially those linked to living with hidden disabilities as "the walking wounded." The third section ("Problems of Social Stigma") explains the problems of social stigma and what can be learned from on point mental illness research for making sense of societal challenges facing TBI survivors. The final section ("Educational Strategies and Using Narrative Media for Combating Stigma") concludes the chapter by examining educational strategies and the use of documentary narrative media for combating and redressing stigmas against this population.

Introduction

The human brain is a powerful organ and is commonly understood as a placeholder of privileged values, including those that are thought of as defining for our personal and human identity. Accordingly, philosopher Francisco Ortega and history of science professor Fernando Vidal have written on the rise of the “cerebral subject” in contemporary, industrialized societies, thereby referring to “an anthropological figure that embodies the belief that human beings are essentially reducible to their brains” (Ortega and Vidal 2007, p. 255). At least since the Enlightenment, a strongly influential strain in ethical theorizing has understood the human self to be a source or loci of unconditional value (Taylor 1989). If this is correct, and if as modern individuals we now are to understand human selves as essentially “cerebral subjects” (Vidal 2009), then it is easy to see how the human brain has come to assume its place as a source of *paramount* value in our culture(s). Ortega and Vidal’s recent book, *Neurocultures* (2011), maps the discourses, images, and practices that trace the social impact of the neurosciences and propel belief in the “cerebral subject” from public policy to the arts, from neuroscience to theology: they surmise that “[t]he new discipline of neuroethics is eminently symptomatic of such a situation” (Ortega and Vidal 2007, p. 255).

Indeed, neuroethics is celebrated as a new discipline, but as a new discipline – and influenced especially by philosophy – some scholars have seen fit to engage in self-reflexive investigations to determine its scope, purposes, and validity (Glannon 2007; Glannon 2011; Levy 2007; Levy 2012; Racine 2010; Roskies 2002). For those who see in the discipline a need for reflexivity (Brosnan 2011; Ahern 2011), considering the ethical implications of embracing or resisting the growing social impact of the neurosciences and creep of “neurocultures” means asking not only local questions about how this novelty might expand or contract what we already value. There is also a need to consider how all this focus on the brain (neuro-centrism) might create, or at least facilitate, certain barriers to overlooked or alternative courses of valuing and caring (see, e.g., Scully 2008) that do not sufficiently, but could perhaps better, command our present and future attention (cf. Racine and Forlini 2010; Outram and Racine 2011). An example of this reflexive approach that includes scoping what is on the horizon without “getting ahead of ourselves”[1] (so to speak) is Éric Racine’s *Pragmatic Neuroethics* (2010; see Racine 2008). Racine maintains that “the need for an interdisciplinary and collective response to ethical challenges in neuroscience *and* clinical care – neuroethics – has surfaced in the past years in response to important *social*, medical and scientific changes” [emphasis added] (Racine 2010, p. ix). One of the main

[1]In this regard, Racine’s work in neuroethics might be read as cutting off the path that slips into looking for answers to mental health in “neuroscience fiction” when relevant progress would seem more likely for the near future by paying greater attention to some of the methods, tools, and resources made available through the social sciences.

challenges for neuroethics, according to Racine – marking a new moral task that indicates a plurality of needs so complex and profound as to require a collective, integrated, interdisciplinary response (Racine 2008) – is the finding of the World Health Organization that the combined global "health burden" of neurological and mental health disorders now matches, if not surpasses, that of any cluster of health conditions (Racine 2010, p. ix; WHO 2006). If neuroethics is to play an important role in addressing the global health burden of neurological and mental health disorders, this importantly would have to be a matter not only for "Research Neuroethics" and "Clinical Neuroethics", but also one for "Public and Cultural Neuroethics" – defined by Racine as the "[e]thical challenges in the public understanding of neurological and psychiatric conditions: public engagement and the cultural representation of mental illness" (Racine 2010, p. 5).

This chapter takes as its focus the topic of traumatic brain injury (TBI) from the perspective of "Public and Cultural Neuroethics." If, as I am suggesting, there is some inflation – or misunderstanding (Glannon 2009:esp. ch.1) – going on with respect to the abovementioned tendency to see ourselves as defined essentially and singularly by our brains (Vidal 2009), what of those whose identities have been (at a minimum) shaken or, as the case may be, severely ruptured by a TBI? Plainly put, what is it to deal with a TBI in a culture with a matrix of social inscriptions fixing the view that "you are your brain" (Gazzaniga 2005, p. 31 qtd. in Ortega and Vidal 2007, p. 256), not simply that "you have a brain" (Vidal 2009)? Does the common experience of dramatic change in the survivor's life course and identity after a TBI (Widzinski 2009; Nochi 1998; Leith et al. 2004, p. 1204) prove correct the belief in the "cerebral subject"?

I want instead to show that there are not-so-new, well-worn, deeply entrenched social and cultural barriers implicated in the trauma and injury commonly experienced in the lives of TBI survivors. In this regard, documentary narrative media (e.g., video and film) is proving to be a promising tool in redressing these disabling, societal impediments.[2] As to the outline, the first section of this chapter ("Traumatic Brain Injury (TBI) and the Situational Context for Survivors") details some basic facts about TBI and the situational context for this patient population, focusing mainly on the USA. The second section ("Mistaken or Misattributed Beliefs About TBI") explains some of the prevalent societal misperceptions of persons living with TBIs, especially

[2]With the term "societal impediments" I would like to make room for understanding the barriers imposed by societies on TBI survivors as including more than just social factors. What is more, the disabling societal factors discussed in this chapter not only have a negative effect on the functioning of TBI survivors but also erect barriers against the possibility for "societies-in-general" from accessing the rich experiences and resources of this unnecessarily alienated population (cf. Scully 2008). Admittedly, this chapter focuses, in the main, on the losses experienced by TBI survivors, though more should be said on the relevant lost benefits to their respective societies (Sherry et al. 2010; cf. Swain and French 2000; The Disability Pride and Awareness Committee 2013).

those linked to living with hidden disabilities as "the walking wounded." The third section ("Problems of Social Stigma") explains the problems of social stigma and what can be learned from on point mental illness research for making sense of societal challenges facing TBI survivors. The final section ("Educational Strategies and Using Narrative Media for Combating Stigma") concludes the chapter by examining educational strategies and the use of documentary narrative media for combating stigmas against TBI survivors and for redressing problems arising from a "spoiled" social identity which marks this population.

Traumatic Brain Injury (TBI) and the Situational Context for Survivors

Depending on the site and extent of the insult (Levin 1993), TBI can involve effects on sensation, cognitive, emotional, motor, and behavioral functioning, (NIH 1998; Evans 2006; BIAC 2013) as well as personality changes sometimes complicated by lack of awareness (McAllister 2008, p. 4). Neurobehavioral sequelae vary in severity, length of time, and clinical manifestations (Riggio and Wong 2009, p. 163) leading to an "enormous range of outcomes" and varied needs on the part of the patient (Whyte 1998, pp. 23–24). Traumatic injuries to the brain are strongly associated with elevated risk of psychiatric conditions such as mood disorders (major depression, mania), anxiety disorders, psychosis, apathy, behavior or dyscontrol disorder, sleep disturbance, headache (Rao and Lyketsos 2000; Riggio and Wong 2009, p. 163), substance abuse (Taylor et al. 2003), and suicide (Teasdale and Engberg 2001; León-Carrión et al. 2012).

The WHO has recognized TBI as a universal public health concern (WHO 2006; McAllister 2008, p. 3; NINDS 2013), with a general incidence in developed countries commonly reported at 200 annually at risk per 100,000 population (Bruns and Hauser 2003). However, these rates are calculated solely on the basis of hospitalized cases and therefore do not include instances where injured persons either do not seek or have access to hospital care. Diagnosis is especially challenging, given that affected individuals may not manifest physical signs of injury. Studies in the past have shown mild TBI to be significantly underdiagnosed (NIHCDP 1999, p. 974). Even modern neuroimaging (e.g., MRI and CAT scans) or brain testing techniques (e.g., EEG) may fail to detect signs of brain injury (DVA 2013). McAllister surmises that "the actual incidence of injury is probably three to four fold larger than the [above] quoted numbers" (McAllister 2008, p. 3; cf. Thornhill et al. 2000).

Around the world, TBI is the foremost cause of death and neurologic disability in children and young adults (WHO 2006, p. 164). Thornhill and colleagues (Glasgow) have reported that approximately half of survivors admitted to hospital with mild or moderate TBI were classified as disabled a year afterwards and three quarters were so classified after a severe TBI (Thornhill et al. 2000). These authors conclude that "[t]he incidence of disability in young people and adults admitted with a head injury is higher than expected. This reflects the high rate

of sequelae previously unrecognised in the large number of patients admitted to hospital with an apparently mild head injury" (Thornhill et al. 2000, p. 1631).

Approximately 5.3 million persons in the USA (~2 % of the population) live with a TBI-related disability (CDC 2013), with an incidence rate estimated to be 150 annually at risk per 100,000 population (Kraus and Chu 2005). From 2002 to 2006 TBI-related emergency department visits in the USA increased by 14.4 % and hospitalizations by 19.5 % (Faul et al. 2010). Even though 75 % of recorded cases in the USA are mild forms of TBI, of 288,009 TBI survivors who were hospitalized in 2003, 124,626 (43 %) developed a long-term disability (Selassie et al. 2008).

Over the past four decades, in developed countries (including the USA), mortality rates have significantly declined with improvements in acute medical management (Arciniegas and McAllister 2008) and advances in trauma and neurosurgical services (McAllister 2008, p. 3; NIH 1998; Marshall 2000; Zink 2001). This has led to a concomitant increase in the population of persons living with disabilities associated with the neurobehavioral and neuropsychiatric disturbances resulting from TBIs (McAllister 2008; Arciniegas et al. 2000; McAllister 1992; Chesnutt et al. 1999, p. 9). Due to the complexity of the effects of insults on the brain, rate of recovery is often slow, with attendant high social, financial, psychological, and medical costs (McClure 2011, p. 85). As the 2006 WHO public health report *Neurological disorders: Public health challenges* maintains:

> The importance of rehabilitation is consistently underestimated, not least because of its cost. It is a regrettable truth that this part of the treatment lacks the drama of the primary treatment and is consequently more difficult to fund. It is nonetheless of great importance since TBI damages young lives for whom rehabilitation is as important for the regaining of function as primary treatment is for the saving of life. (WHO 2006:170)

Given the enormous range of outcomes possible with TBI, the goals of rehabilitation are very broad (Whyte 1998, pp. 23–24). Traditionally, in the USA, the focus has been "quite narrowly centred on acute medical restoration" (Leith et al. 2004, p. 1191; NIHCDP 1999). More recently, there has been a greater shift towards post-acute, community-based service delivery with the aim of integrating medical with psychosocial and environmental supports (Sloan et al. 2004; Willer and Corrigan 1994; Leith et al. 2004; Hibbard et al. 2002). However, as the need for services and supports becomes less and less like that which medical institutions are set up to deliver, funding for these unmet needs becomes ever more scarce (Whyte 1998, pp. 23–24). For instance, across the state healthcare systems in the USA, inpatient trauma and rehabilitation services tend to be reimbursed, while a large portion of outpatient services to assist community integration and facilitate well-being are either not adequately funded or not funded at all (Reid-Arndt et al. 2010, p. 142). Sadly, it is not uncommon that "efforts towards integrated care . . . end once a person with TBI leaves the medical arena" (Leith et al. 2004, p. 1192). The hardships for TBI survivors and their families are further compounded by the fact that recovery is oftentimes a long and incomplete process. To address these concerns

and meet the challenges of this growing public health concern, there is obviously a need to grow stakeholder as well as general public support for this population (Bérubé 1998, 2002, 2003). As Reid-Arndt and colleagues explain:

> Substantial efforts to educate others regarding the variety of possible outcomes following TBI are essential, as problems predicting the long term sequelae an individual may experience following a TBI complicates efforts to envisage needed programmatic services and supports. It is this complex nature of TBI, indeed, the difficulty comprehending the broad spectrum of consequences of TBI, which makes advocates' task difficult. (Reid-Arndt et al. 2010:138)

Mistaken or Misattributed Beliefs About TBI

In spite of the prevalence and gravity of brain injury, research indicates that nonexpert health professionals and the general public hold inaccurate or inadequate knowledge about TBI (Chapman and Hudson 2010, p. 797; Swift and Wilson 2001; Redpath and Linden 2004, p. 867), with historically very little progress in these matters (Hux et al. 2006, pp. 547–548; Guilmette and Paglia 2004, p. 188). For example, a US study by Gouvier and colleagues published in 1988, replicated by Willer et al. in 1993, with a follow-up again by Guilmette and Paglia in 2004, revealed that a high proportion of study participants believed that TBI survivors only suffer temporary cognitive deficits and that complete recovery from head injury is possible, contrary to expert opinion (Swift and Wilson 2001, p. 150; Chapman and Hudson 2010, p. 797; Hux et al. 2006, p. 550).

A prevailing reason that the changes in personality and new life challenges of the survivor are so difficult for others to understand and accept is that a large proportion of the effects of TBI, unlike physical injuries, remain invisible or not readily open to view (BIAC 2013). What is more, some of the effects of TBI – e.g., fatigue, poor concentration, memory loss, speech difficulties, anxiety, mood swings, and even intermittent aggression – may sometimes be seen in people without brain injuries, though not to the same degree or frequency (Guilmette and Paglia 2004; Matthews 2000). Even so, as with other nonvisible disabilities, "people may believe that there is nothing wrong with the injured persons" (McClure et al. 2006, p. 1029; see Matthews 2000; Miller and Sammons 1999). Expectations of TBI survivors are then based upon their usually intact, overt physical appearances of being normal (Swift and Wilson 2001; McClure et al. 2006). In this way, survivors become members of the "walking wounded." As a result, people who are not familiar with brain injury and lack awareness of survivors' psychiatric challenges form expectations for survivors' behavior as if they were neurotypical, oftentimes misattributing those symptoms that are the result of injuries ["actual cause" (Kelley 1967)] to other factors or causes (Leith et al. 2004, p. 1204; McClure et al. 2011; McClure 2011).

In the early stages, physical wounds or bandages on the head may indicate the experience of an insult to the brain, but TBI sequelae normally persist well past the point when physical markers of head injury are still readily apparent

(McClure et al. 2006, pp. 1029–1030). The literature reports that in cases where survivors lack visible markers of TBI, the resulting cognitive and behavioral sequelae are oftentimes misattributed to the everyday exigencies of life, life stage (Osborn 1998; Phillips 2000), or personality of the individual (Manchester 2006; McClure et al. 2006; McClure 2011, p. 86). Understandably, it is a small step from this to the added inference that the effects will not persist in the future (McClure et al. 2011, p. 395).

Research has also shown that not only the invisibility of the injury, but also the "dimension on which the injured person's behaviour is seen as abnormal," count as salient factors that distinctly affect attribution patterns (McClure 2011, p. 87). While family and expert professionals who know the survivor's history will usually make attributions based on how normal the TBI-related behavior presents as compared to the pre-injury state, other observers (absent this knowledge) will commonly make attributions simply according to compliance of the presenting behaviors with cultural norms (McClure and Abbott 2009; McClure et al. 2011, p. 393). Swift and Wilson have reported that even some hospital staff, family, friends, and the general public who experienced "inappropriate" behaviors from TBI survivors and who knew them to be brain injured, nonetheless failed to consider TBI as a possible source of explanation for these behaviors (Swift and Wilson 2001, p. 159). Swift and Wilson (2001) do not give specific examples here (at p. 159) of the behaviors judged to be inappropriate. However, later in their article they explain that:

> Although the health professional, unlike the lay person, is aware in many cases that the patient presenting with problems has a history of brain injury, many misconceptions attributed to health professionals who were not experts in the field of brain injury were similar to those held by the general public. These included inaccurate beliefs about: time span and extent of recovery; ability to return to work; behavioural symptoms being unrelated to the brain injury; the interpretation of physiogenic symptoms as psychological; the misinterpretation of motivation problems as laziness; and trivializing symptoms and their impact.[3] (Swift and Wilson 2001:160)

Hence, misattribution and/or discounting the injury as an explanation for behavioral and psychosocial sequelae leads TBI survivors to feel misunderstood, compounding their experience of adversity (McClure et al. 2006, p. 1029; McClure 2011, p. 90). Misattribution to transient causes such as life stage (e.g., adolescence) or personality may feed into expectations[4] for a recovery that is unrealistically swift and complete (Swift and Wilson 2001; McClure 2011, p. 87) – a possible "setup" for the survivor's perceived sense of failure. Such a scenario can work to compound survivor distress and frustration (McClure et al. 2006; McClure 2011) with the risk of further contributing to their existing deficits, thus impeding the recovery process (Guilmette and Paglia 2004, pp. 183–184). An additional misconception across the lay public (Gouvier et al. 1988), less experienced healthcare professionals (Ernst et al. 2009), as

[3] *Cf.* Gouvier et al. (1988) and Springer et al. (1997) for discussions of misperceptions of TBI survivors by their family members.

[4] See McClure et al. (2011) and Stone and Colella (1996) for a discussion of how people's expectations affect outcomes for persons with invisible disabilities.

well as educators (Farmer and Johnson-Gerard 1997) is that recovery is largely contingent upon the amount of effort exerted (to this purpose) by the survivor (McClure 2011, pp. 86–87). Hux and colleagues have reported a dramatic increase since 1993 in the tested public's misperception of the feasibility of complete recovery from severe TBI:

> Specifically, the public was largely incorrect in recognizing that complete recovery from severe brain injury is not possible, regardless of a person's desire for or commitment to self-improvement. Although 84.66 % of the 1993 respondents did not endorse this misconception, only 27.99 % of today's public recognized the fallacy of this notion. (Hux et al. 2006:550)

In general, then, many people (including healthcare professionals and service providers) either do not recognize, or actively minimize, the diversity of resultant cognitive difficulties and the broad impact of TBI-related injuries on the physical, psychological, emotional, behavioral, and social realms of the TBI survivor's life (Leith et al. 2004, p. 1204; see Swift and Wilson 2001; Guilmette and Paglia 2004; Hooper and Callahan 2001; McClure 2011, p. 90).

Problems of Social Stigma

Physically surviving a TBI is just the beginning of what is usually a lifelong process of adjustment and accommodation (Miller and BIRC 2009, p. 65). Researchers have consistently viewed the psychosocial challenges of TBI – chronic challenges related to the survivor's cognition, emotional functioning, and behavior in connection with interpersonal relationships, school, or work (NIH 1998) – as the most problematic for rehabilitation and critical to successful post-injury reentry into the community (Morton and Wehman 1995). As time proceeds post-injury, the aforementioned diversity of sequelae (including depression, aggression, anxiety, and communication disorders) contributes to the constriction of the survivor's social networks (Linden et al. 2005, p. 1011) in tandem with increasing intensity of time spent with family (Corrigan 2006, para.6; see Jacobs 1988; Kozloff 1987; Brzuzy and Speziale 1997). As Corrigan notes: "This constriction is not optimal for the individual or the family, and both end up feeling isolated" (Corrigan 2006, para.6; see Morton and Wehman 1995; Wallace et al. 1998).

In this regard, the societal impediments faced by TBI survivors and their families are in no way new:

> To borrow from the literature on mental illness, the attitudes society holds towards the mentally ill affects the development of social relationships (Thomsen 1992; Morton and Wehman 1995). Individuals perceived as being different are often treated with distrust, a lack of tolerance, and fear. (Linden et al. 2005:1011; see Guilmette and Paglia 2004; Willer et al. 1991)

A recent report (from the UK) by Linden and Boylan (2010) found all participants in their qualitative study typically used negative labels (e.g., perceptions of aggressiveness, dependency, and general unhappiness) when asked to describe TBI survivors

(see Linden and Crothers 2006; Linden and McClure 2012). In New Zealand, McLellan and colleagues tested for explicit and implicit negative attitudes (within the community) towards TBI survivors and if the terminology used ("head" vs. "brain") injury exacerbated negativity. Participants rated a hypothetical young adult subject described as having a "brain"/"head" injury more negatively than the same subject described as having a limb injury due to a car accident experienced during childhood. According to McLellan and colleagues, the negative attitudes observed were:

> openly endorsing less desirable characteristics to a young adult who experienced a brain injury as a child compared with a young adult who did not. In particular, they were regarded as less mature, intelligent, flexible, polite, and employable. In addition . . .using the term "brain injury" resulted in the individual being judged more negatively than when the term "head injury" was applied to the same injury event. (McLellan et al. 2010:708)

General discrimination against persons with disabilities is a widespread phenomenon well documented in the literature, which is arguably more intense and with less protections for persons with "more-mental-than-physical" disabilities (see Martinson 1998). In the mental health literature, research shows that the public hold significantly more negative attitudes and disapprove more strongly of persons with psychiatric disabilities than persons with related conditions of physical illness (Corrigan and Watson 2002a, p. 17; Corrigan et al. 2000; Socall and Holtgraves 1992; Weiner et al. 1988; van 't Veer et al. 2006). Corrigan and Watson point out that a prevalent reason for this is the widespread public belief that, unlike physical disabilities, persons with mental illnesses are in control and therefore responsible for causing their disabilities (Weiner et al. 1988; Corrigan et al. 2000; cf. Linden et al. 2007; Redpath et al. 2010). Research studies have shown that respondents "are less likely to pity persons with mental illness, instead reacting to psychiatric disability with anger and believing that help is not deserved" (Corrigan and Watson 2002a, p. 17; Socall and Holtgraves 1992; Weiner et al. 1988; Albrecht et al. 1982). Also, one Canadian study of knowledge about the sequelae of minor head injury and whiplash showed that lay persons may be significantly more sympathetic to complaints of physical symptoms resulting from an automobile accident in contradistinction to expressions of the same for cognitive difficulties (Aubrey et al. 1989). In this regard, Schomerus and colleagues have noted that attempts to impress upon the public that mental disorders are illnesses "like any other" (with biological correlates) may have been successful in promoting the acceptance of medical treatment for such, but has seemingly done little to promote greater social tolerance and positive acceptance of persons with neurological and psychiatric conditions (Schomerus et al. 2012, p. 450). Thus, TBI survivors, their families and support teams would appear to face many similar social challenges as those confronted by relevant populations living with mental illnesses (Redpath and Linden 2004, pp. 862–863). As Byrne notes: "Mental illness, despite centuries of learning and the 'Decade of the Brain', is still perceived as an indulgence, a sign of weakness" (Byrne 2000, p. 65).

Simpson and colleagues undertook a cross-cultural qualitative research project and found a common experience of problems with stigma and social isolation for TBI survivors and their families from all three backgrounds studied: Italian,

Lebanese, and Vietnamese (Simpson et al. 2000). Indeed, stigma has been identified as an issue "particularly associated with mental disorders and brain injury" (Redpath and Linden 2004, pp. 862–863; Phelan et al. 2011).

According to Goffman's theory, stigma is an attribute, behavior, or reputation that is socially discrediting insofar as it causes an individual to be classified by others according to an undesired, rejected stereotype in contradistinction from an accepted, normal one (Goffman 1963, p. 5). Stigmatizers make assumptions, attribute undesired qualities, and affix labels that assign "differentness" to those stigmatized, thus serving to distinguish the stigmatized from the "greater" society. But the differences so entrenched are for Goffman a matter of perspective, not reality: stigma arises because of the gap between virtual social identity and actual social identity (Byrne 2000, p. 65; Theriot 2013, p. 122). As we have seen with the case of TBI survivors, the resulting "tainted" (or "spoiled-in-advance") social identity negatively affects people's willingness to form social relationships with individuals that bear the marks of stigma and can intensify survivors' experience of social discrimination, isolation, and withdrawal (Theriot 2013, p. 122; cf. Corrigan et al. 2000). But for stigmatization to be effective, the stigmatized individual must internalize society's devaluation, owning the negative stereotype, thus recognizing her/his "spoiled" identity as a social reality (Jacoby et al. 2005; WHO 2006, p. 20; Burris 2008, p. 474). Goffman argues:

> The central feature of the stigmatized individual's situation in life is a question of what is often, if vaguely, called "acceptance". Those who have dealings with him fail to accord him the respect and regard which the uncontaminated aspects of his social identity have led him to anticipate receiving; he echoes this denial by finding that some of his own attributes warrant it. (Goffman 1963:8; cf. Burris 2008:474)

As such, "[s]elf-stigma results in a loss of self-esteem, diminished self-efficacy, and increased reticence about participation in social interactions" (Holmes and River 1998, p. 232). Not only is it hard for TBI survivors to face a society that misunderstands and devalues them; the net effect of stigma is also isolating, making for a seriously debilitating web of societal impediments that have historically prevented persons with serious psychiatric and neurological conditions from seeking and securing employment, assistance with living, adequate housing, and necessary healthcare (Baun 2009; Corrigan et al. 2000; Corrigan and Watson 2002a; Holmes and River 1998; Yang et al. 2008).

Educational Strategies and Using Narrative Media for Combating Stigma

The negative consequences of mistaken or misattributed beliefs, as well as generalized effects of stigma relevant to TBI, argue for various educational measures (Guilmette and Paglia 2004; McClure et al. 2011, p. 395) – including those targeting the general public (Mayville and Penn 1998, p. 250) – in order to foster an environment more conducive to social inclusion and support for TBI survivors (Scior et al. 2013; Walker and Scior 2013). As Peter Byrne, cochairman

of media projects for the UK Royal College of Psychiatrists' *Changing Minds* anti-stigma campaign, notes, "the starting point for all target groups and at every level is education" (Byrne 2000, p. 67; see WHO 2006, p. 21). Every educational intervention, as Byrne further explains:

> must convince its target group of the importance of stigma/discrimination, challenge stereotypes in ourselves and others, and pursue the ongoing task of unravelling the nature of prejudice. These three separate tasks are summarised in the *Changing Minds* slogan: "Stop, think, understand". (Byrne 2000:67)

In the literature, it has been argued that education can provide what is needed by the lay public to make more informed decisions about mental illness (Corrigan 1998, p. 217). As Corrigan and Watson (2002a) note, several studies have shown that participation in programs that strategically provide information on mental illness resulted in the lessening of negative stereotypes and improved attitudes about persons with the relevant conditions (Corrigan et al. 2001c; Morrison et al. 1980). But as Byrne and Corrigan and Penn contend, "closing the knowledge gap" on discrediting psychiatric stigma is only part of the answer (Byrne 2000, p. 68; Corrigan and Penn 1999).

The degree of familiarity with mental illness is a major impact factor for stigmatizing attitudes and behaviors (Corrigan et al. 2001b). Not simply greater knowledge but also *greater experience* with mental illness has been significantly correlated with less frequent (expressed) desire for social distance (Angermeyer et al. 2004; Vezzoli et al. 2001; cf. van 't Veer et al. 2006). Accordingly, researchers have consistently found personal contact to be most effective at reducing stigma associated with mental illness (Burris 2008; Corrigan et al. 2001a, c; Kolodziej and Johnson 1996; Lyons and Ziviani 1995; Penn et al. 1994, 1999; Phelan and Link 2004). This approach is now informing the large-scale social marketing efforts of the (US) *National Consortium on Stigma and Empowerment* (Corrigan 2011) and England's *Time to Change* campaign as associated with mental illness (Evans-Lacko et al. 2012, 2013).

The findings of research into stigma related to TBI are in line with what has been given here as evidence for combating stigma of mental illness. A recent study by Redpath and colleagues confirms that research participants who knew someone with a TBI "expressed less prejudice and were more likely to interact with the protagonist than those who didn't know someone with TBI" (Redpath et al. 2010, p. 808). Moreover, healthcare professionals who knew a TBI survivor were more likely to express more helping behaviors towards other TBI survivors (Redpath et al. 2010). McLellan and colleagues observed that "when people have more knowledge about or experience with brain injury, they are less likely to endorse negative stereotypes" (McLellan et al. 2010, p. 705),[5] and only those persons tested who were unfamiliar with TBI demonstrated a negative implicit bias. These TBI researchers concluded this study, saying:

[5]McLellan and colleagues' study also showed that test subjects unfamiliar with TBI and its effects had unconscious negative attitudes towards patients with TBI (McLellan et al. 2010; referenced by Phelan et al. 2011, p. 178). Burris has noted that diseased-based stigma may operate, in the main, through automatic emotional reactions and that familiarity may serve to reduce these reactions like the process of desensitization through exposure can reduce evolutionary-based phobias (Burris 2008, p. 475).

> Initiatives that increase the public's familiarity with brain injury and realistic sequelae may decrease negative evaluations. . . .Our findings suggests [sic] that negative evaluations of people with brain injury are not necessarily underpinned by an automatic or deep-seated bias, but rather are due to an openly held belief that brain injuries result in personality changes or deficits that render a person as less desirable. The explicit nature of the bias means it is reasonable to speculate that such negative attitudes may be more easily open to education, communication, and therefore amelioration. (McLellan et al. 2010:708; Rydell et al. 2007)

Consumer contact[6] is proving to be a most promising strategy in redressing stigma associated with psychiatric and neurological conditions (including TBI), especially when it is "targeted, local, credible, and continuous" (Corrigan 2011, p. 824). In the disabilities literature, Walker and Scior's review notes that "several studies have found a positive effect of direct contact on attitudes towards those with intellectual disabilities" (Walker and Scior 2013, p. 2201; McConkey et al. 1993; Rillotta and Nettelback 2007; Roper 1990). But while direct contact is very valuable, it may prove extremely hard to achieve on a large scale (Walker and Scior 2013, p. 2201) unless many more individuals come forward in public places (e.g., their workplaces) to disclose their experience of living with a stigmatized condition. Obviously this prospect would be risky for these individuals, given the prevalence and high costs (e.g. discrimination, loss of status, or loss of opportunities) associated with social stigma related to psychiatric and neurological conditions (Watson and Corrigan 2005, p. 291). This has led some anti-stigma activists and researchers to strategize the use of relevant film footage or video clips of contact in order to reach larger audiences (Dougall et al. 2012; Knifton et al. 2010; Quinn et al. 2011; Corrigan et al. 2007).

In this regard, there is building evidence that mere exposure can be an effective way to change negative and prejudicial attitudes (Walker and Scior 2013, p. 2201; Pettigrew 1998; Pettigrew and Tropp 2006; Zajonc 2001). The literature demonstrates specific successes with indirect contact interventions to improve attitudes to persons with intellectual disabilities or mental illnesses (Walker and Scior 2013; Carsrud et al. 1986; Hall and Minnes 1999; Smedema et al. 2012; Clement et al. 2012). One study by Corrigan and colleagues showed that a filmed version of contact led to greater mental illness stigma improvement (with positive changes on measures of pity, avoidance, and segregation) than an educational videotape without the additional indirect contact piece (Corrigan et al. 2007). Another study by Reinke, Corrigan, and colleagues showed relevant parity of improvement whether contact was presented in vivo or on videotape (Reinke et al. 2004; cf. Faigin and Stein 2010).

The use of film or video may prove additionally useful for reaching members of the lay public who might otherwise not be comfortable with, or even afraid and distrustful of (Linden and Crothers 2006), educational formats that include direct contact with persons affected by TBI (cf. Ritterfeld and Jin 2006). Arguably, films have the capacity to put viewers in contact with "a surrogate reality without having

[6]See Allport (1954), Pettigrew (1998), Pettigrew and Tropp (2000), and Couture and Penn (2003) for explanations of the intergroup contact theory hypothesis according to which direct interaction between members of the "in-group" with the "out-group" is thought to improve prejudicial attitudes (Walker and Scior 2013, p. 2201). See also Dovidio et al. (2003) and Pettigrew and Tropp (2008).

to take part in it" (Horsley 2009, p. 2), providing an opportunity to deal with stigma in a way that is importantly nonthreatening (cf. Watson and Corrigan 2005, p. 282; Macrae et al. 1994). As one interviewee reflecting on the *Scottish Mental Health Arts & Film Festival* put it:

> I like film anyway but I just think it's important to have that ability to reflect on issues or situations that actually happen in real life, in a safe sort of way. I suppose it makes it a bit safer because you're watching it on a film because you're not watching a real scenario, but it's not real and you can go away and think about it. (Dougall et al. 2012:131)

Across the USA today, narrative video media and documentary film are being used as tools of indirect (yet personal) contact to reduce stigma and foster a more positive social identity for TBI survivors. Part of this upswing is attributable to the fact that new technological advances in digital filming and computer-based editing have made film vignettes and documentaries increasingly affordable and easier to view and produce. Video capabilities through the internet have also made these materials widely accessible (Volandes 2007, p. 680). Accordingly, the (US) Center for Disease Control Injury Center and CDC Foundation have partnered to sponsor *Heads Up TBI Film Festival*, an online collection of TBI testimonials. TBI stakeholder participants are encouraged to create a video and upload it to *YouTube* in order to (i) share their "stories, experiences, successes, challenges, goals, memories and the hopes that motivate [them] each day" and (ii) "join a supportive community and share [their] ideas" (CDC Foundation TBI 2013). The CDC maintains that the goal of the film festival is to give participants a chance to "lend [their] voices so that TBI is no longer a 'silent epidemic'" (CDC Foundation TBI 2013). At the time of writing, 58 personal videos are listed with *Heads Up*, and a general search of *YouTube* for the terms "brain injury" and "story" yielded about 49,400 results.

Video narratives in this way are serving TBI survivors to connect and learn from one another and to promote their public visibility across a potentially wide spectrum of viewers. This phenomenon could be read as being "in step with" social movements across minority groups who have historically used storytelling as an important political tool in assisting to share experiences "that otherwise are not easily understood or appreciated" (Young 1997, p. 71). The importance of first-person perspective reporting (Ward and Meyer 1999, p. 137) and self-advocacy for taking greater control of public understanding of minority status social group identity is well known (Baun 2009; Cort 1987; Wilson 1999). Arguably these stories are working to change the face of TBI and, to borrow the words of longtime TBI advocate Constance Miller, they are fitting into a wider movement "to elevate the status of TBI from one of pity and shame to one of admiration and respect" (Miller and BIRC 2009). In this regard, these video narratives are what feminist bioethicist Hilde Lindemann Nelson has theorized as counterstories – namely, stories that provide a means through which to resist imposed misperceptions and misattributions that diminish agency, stories of self-definition that are "developed in response to the twin harms of deprivation of opportunity and infiltrated consciousness" (Lindemann Nelson 2001, p. 9).

If, as Byrne explains, "part of coping with stigma is fighting stigma" (Byrne 2000, p. 70), then counterstories provide an appropriate analytic for making sense of the growing movement within TBI communities to provide narrative repair (Lindemann Nelson 2001, p. 20) as a way to cope with not just damaged brains but damaged identities. This theme traces through the video documentary, *Brain Injury Dialogues*, which has been written and produced by TBI survivor Rick Franklin and documentary moviemaker Lyell Davies. The film works at bringing the world of brain-injured persons, "often 'invisible' on several levels, into the consciousness of the general public" as well as other TBI survivors, their families, and caregivers (Widzinski 2009). As the filmmakers visit with other TBI survivors, viewers see and hear "how survivors learn to deal with life after brain injury by means of personal, medical, and even political strategies," with a particular focus on the latter. In the "Filmmaker Statement" (tab) posted on the *Brain Injury Dialogues*-dedicated website,[7] Franklin explains that:

> one of the key messages in this video is the need for community support for survivors. . . .A second message . . .this documentary offers is how essential it is for all of us to better recognize the needs of brain injury survivors. For this to happen, we as brain injury survivors (with the help of disability rights, non-injured advocates, etc.) need to organize ourselves and both demand the accommodations we need, and reach out to help those also afflicted with this kind of injury. (Davies and Franklin 2010a)

Indeed, as featured TBI self-advocate and disabilities scholar Mark Sherry notes: "Peer support is critical to sorting out identity and gaining recovery" for survivors (Sherry et al. 2010), thus ameliorating some of their needs for connectedness and belonging (Leith et al. 2004, p. 1204). In this regard, the featured survivor support meetings include dialogue that parallels the late 1960s women's movement and its consciousness raising efforts which found that "the personal is political" (Hanisch 2006, p. 4). Indeed the *Brain Injury Dialogues* shows that when TBI survivors share their experiences of frustration, unhappiness, and anxiety, it seems that wider patterns of social stigma and a lack of societal concern and respect for their rights structure these personal, once seemingly private, stories and problems (cf. Young 1990, pp. 153–154). In this film, political dimensions emerge through social dialogue across survivors' stories which are critically explored together, with many personal problems revealed as public issues (Galvin 2005, p. 409). The film builds to a political conclusion that even though "no two brain injuries are alike" and that services and supports need to be personalized (Davies and Franklin 2010b, p. 14), solidarity and collective action are paramount, notwithstanding survivors' individual differences. Building a positive, cohesive, social identity for TBI survivors is also portrayed as politically important for gaining proper public recognition of survivors and regaining

[7]The website features a DVD transcript (in English), a Spanish translation of the transcript, special interview footage with TBI self-advocate and disabilities scholar Mark Sherry, TBI "Links of Note" (tab), reviews of the film, a link to the *Brain Injury Dialogues* Facebook page, and posted comments. See http://www.braininjurydialogues.org/.

public control of their lives (Sherry et al. 2010, p. 3; cf. Corrigan 1998, p. 215; Ward and Meyer 1999, p. 134). Mark Sherry's closing words of the film are unmistakably a battle cry to make the personal political in order to surmount forces of social stigma in the dominant culture:

> We, we in our hands, hold our fate. If we don't stick together, if we don't advocate, if we don't build something that's, that's much bigger than my little stay in hospital. . . if we don't say 'this was a really important thing but sometimes the system let me down, and for the next person, I've gotta make sure this doesn't happen'. Then we're letting down the next person in the same bed that we were. And that person really has far more in common with you than you care to realize. And that person is your brother and sister. Because they, they really are you. And, you know, what, what we, what we don't think about. . . what we, what we're trained in society to think about is this; I'm not like. . . I'm not like the person who's. . . down. I'm not like the person who's homeless. I'm not like the person who's psychotic. I'm not like the person who's "epileptic", or whatever. You know, I want to say the absolute opposite. I want to say to anybody who ever hears me. "Crazy?", I'm crazy. Epileptic? I'm "epileptic". Using a catheter? I'm using a catheter. Unable to breath for yourself? I'm unable to breath for yourself. Anything abject, anything disrespected, that's me. That's bed number two. That's bed number three. That's bed number four. That's us. That's our family. If we don't stick together. . . we, we live or die by that. (Davies and Franklin 2010b:15–16)

The *Brain Injury Dialogues* is thus an attempt to foster a new social story and social identity for TBI survivors. TBI survivors, on account of having (most commonly) invisible disabilities, are sometimes able to pass (Goffman 1963) for normal and therefore escape, at least initially, automatic stigmatization. There may be social incentives to conceal their disability to avoid stigmatization, but the damaging consequences include failing to have others recognize and accommodate their non-neurotypical needs (McClure 2011, p. 88; see Livneh et al. 2001; Matthews 2000), not to mention internalizing all of the pressures of maintaining social appearances to the contrary. The new forms of documentary narrative media just mentioned are providing opportunities and support to TBI survivors for managing their public identities and surmounting a state of "discreditable" stigma and self-stigma (Goffman 1963). In other words, the new forms of narrative media, though still not without social risk (cf. Corrigan and Watson 2002b), are providing advocates with an opportunity for "coming out" and publicly claiming TBI survivor status unashamedly as persons with otherwise invisible disabilities. As Mark Sherry puts it: "Brain injury pride. . . that's a completely different way to look at brain injury. To not focus [on] what's been lost, or to feel like less of a person because of it. But instead to take pride in who we've become after our injuries" (Davies and Franklin 2010b, p. 14; cf. The Disability Pride and Awareness Committee 2013).

Conclusion

As we have seen in this chapter, there are risks of a "spoiled" and/or "negative" identity (see Goffman 1963) as per societal barriers attached to the experience of stigma, social distancing, withdrawal, and isolation of TBI survivors. In a culture that puts such emphasis on the view that "you are your brain" rather than "you have

a brain" (Vidal 2009; Ortega and Vidal (2011); Ortega and Vidal 2007), it may seem that fixing the brain will fix the person. But as we have seen in this chapter, much of what makes for the trauma and injury suffered by TBI survivors – much of that which stands in the way of them learning how to repair and perhaps embrace their ruptured identities – is socially constructed in the form of stigma directed against this population. Swift and Wilson have aptly pointed out that "in the long term, brain injury may be conceptualized as a state which requires a careful re-negotiation and adaptation of the identity of the afflicted individual (Judd and Wilson 1999) rather than a condition which can be cured or controlled" (Swift and Wilson 2001, pp. 152–153). The fact that TBI often involves "hidden disabilities" makes matters of adaptation particularly precarious (cf. Pellerin et al. 2011). It is a hope that neuroethics will help to echo the call, already present in the mental illness and intellectual disabilities literature, to acknowledge that our brains and persons are socially situated (DesAutels 2010) and thus grow responsibility beyond the individual and family unit to communities and the wider public in order to provide the needed adjustments and accommodations for this population (Davies and Franklin 2010b; Sherry et al. 2010). Importantly, securing the needed adjustments and accommodations is an interactive and interpersonal process. Some of the new documentary narrative media platforms as directed by survivors represent promising endeavors to begin redressing some of their experiences of social and self-stigma. As such, they are providing emancipatory opportunities for claiming a new kind of social story and public identity for TBI survivors.

Neurotheology

Neurotheology

96

Andrew Pinsent

Contents

Abstract

Neuroscience studies many of the conditions and concomitants for the exercise of those intellectual and moral powers usually considered most specific to the human person. The notion of the person is also central to what is called revealed theology. For this reason and others, prospects for neurotheology seem promising, despite the difficulties of demarcating the proper scope and methods of the field. An emerging theme is the special role of the non-dominant hemisphere in theology and religion. In addition, although strongly reductive interpretations that "explain away" theological matters are likely to attract ongoing interest, there are more expansive modes of interpretation. For example, the embodied cognition that is a central theme of modern neuroscience may have surprising parallels with a subtle, pre-Cartesian tradition of theological anthropology, offering new perspectives on human action and flourishing.

Introduction

Neurotheology, which encompasses the study of matters at the intersection of neuroscience and theology (Newberg 2010), seems to offer intriguing prospects for research, but the challenges begin with demarcation of the field. The first definition of "theology" in the *Oxford English Dictionary* (Simpson 2013) begins, "The study or science which treats of God, His nature and attributes, and His relations with man and the universe; 'the science of things divine' . . .," the term "science" being intended in the classical and medieval sense of *scientia*, which pertains to knowledge that is demonstrated from first principles. By this definition, the subject matter of "theology" overlaps at least in part with that of philosophy. Aristotle remarks (*Metaph*. I, 2, 983a8–10), "God is thought to be among the causes of all things and to be a first principle" (Ross 1924), and "theology," "metaphysics," and "first philosophy," the study of first causes, were practically synonymous in his philosophy. Indeed, this close association is arguably also the reason why philosophical reflection on physics, the modern science that generally touches most closely on issues connected with "first causes," has long been regarded as offering a privileged opportunity for consideration of questions of "natural theology."

Although controversy remains about what, if anything, can genuinely be known about divine matters from the study of the natural world by natural means, there is no doubt that much of the core theological content of Christianity, to give an influential example, is considered within the perspective of faith to be unknowable even by the most refined exercise of human reason in the absence of a direct or indirect revelation from God. Such content is the subject matter of "revealed theology," the ordered study of what has purportedly been divinely revealed about God's relations to human beings and the universe. Among the objects in the world available for empirical study by science, it is embodied persons that are arguably most central to this revelation, since God purportedly communicates such matters either directly to persons or indirectly via other persons, for example, by testimony. Persons are also central to the metaphysical issues of theology. Indeed, this relationship is symbiotic, since the term "person" denotes a supreme principle and arguably the unique metaphysical principle to have emerged from revealed theology, originally to articulate the doctrines of the Trinity and Incarnation when the tools of classical philosophy proved inadequate (Spaemann 2006). Persons are also of central interest to the ultimate purposes of revealed theology according to its own terms, namely, a supernatural mode of human flourishing. This flourishing has been understood in much of the Western tradition, as articulated, for example, in the *Confessions* of St Augustine, as an interpersonal relationship with God culminating in divine friendship.

Since neuroscience provides new and powerful means for exploring what it means to be an embodied human person, there would appear to be considerable potential in the intersection of neuroscience with theological questions. In particular, neuroscience studies many of the conditions and concomitants for the exercise of those intellectual and moral powers usually considered most specific to the human person, shown not least in the existence of the discipline called "theology."

Challenges of Neurotheology

Despite the *prima facie* possibilities for a fruitful interaction of neuroscience and theology, considerable care is needed since neurotheology inherits a host of well-known intellectual hazards from other attempts to apply the findings of neuroscience to the humanities. Such risks include, for example, the temptation to mix the language of psychological powers such as "understanding" with those of the neural conditions and concomitants for the exercise of such powers. Additional potential for confusion, especially in theological matters, arises from the common tendency to transpose Cartesian language into the description of the brain-body relationship ("crypto-Cartesianism," cf. Bennett and Hacker 2003), along with the widespread but erroneous assumption that any view of the world that holds that human beings have immortal souls necessarily presupposes Cartesianism.

Another major challenge is the proper demarcation of a field devoted to the intersection of neuroscience and theology, not least because theology is often confused with religion and there is a well-known difficulty in defining "religion." For example, a focus of neurotheology is sometimes assumed to be the neuroscientific correlates of religious experience, but even a cursory glance at one of the influential works of theology, such as the *Summa theologiae* of Thomas Aquinas, shows that much of the discipline does not involve the study of purported experience, but reasoning about the complex consequences of such experiences in the world. Neurotheology might be better defined therefore as the discipline that addresses the neural conditions and concomitants involved in cognition, reasoning, and attitudes regarding specifically theological matters, which covers a vast range of possible topics. Yet it should be noted in passing that a broader sense of the field would also have to encompass topics that are usually studied independently of theology, especially in ethics, but in which theologians take a special interest or which take on subtly different meanings and priorities from a theological perspective. Some of the many examples include free will, responsibility, and consciousness. An even broader interpretation might encompass ethical questions arising from the treatment of the human person in the conduct of neuroscientific research.

Since even a "narrow" sense of neurotheology is extremely wide-ranging, the chapters of this section have been chosen to represent the key topics and styles of approach at the present time, ordered roughly in terms of increasing complexity of the theological subject material. Michael Trimble examines what can be said about the neuroscience of some kinds of basic religious experiences associated, for example, with sensed presences, acquisitions of information by certain atypical means, and distortions of time. Aku Visala reviews some of the development and multiple meanings of neurotheology, as well as providing a critical evaluation of the problems of translating the implications of neuroscientific work on basic religious experience into the complex conscious, volitional, emotional and experiential aspects of lived religious traditions. Adam Green examines some of the ways in which religious models or conceptual frameworks for understanding the world both shape and are shaped by cognitive processes. Iain McGilchrist draws from his extensive work on the asymmetric, complementary cognitive capacities of the two

hemispheres of the brain, examining implications about the inherent limitations of propositional descriptions and the value of images, metaphors, and narratives in acquiring, evaluating, and communicating religious knowledge that transcends what is already familiar. A final chapter examines how neuroscience can help interpret an account of ultimate human flourishing from a specifically theological perspective. In particular, this chapter examines recent work on the second person in experimental psychology and social neuroscience that has addressed a long-standing problem in moral theology, with implications for a new virtue ethics with a second-person perspective.

Emerging Themes in Neurotheology

Given the comparative novelty of the field, warnings about misinterpretation, and the range of complex issues covered, it might be unwise to express too many general conclusions about the findings of neurotheological research to date. Yet certain consistent themes seem to be emerging and are expressed in more detail in the chapters that follow.

The first of these themes coalesces around the recognition and importance of distinct modes of human cognition. The notion of distinct ways of grasping truth is not new of course, and can be discerned in the classical and medieval distinctions between *intellectus* (“understanding”) and *scientia*, noted previously, as well as distinct words in many languages for “to know,” such as *cognoscere* and *sapere* in Latin, and *kennen* and *wissen* in German. What neuroscience is adding, however, is insight into what happens when the exercise of certain cognitive powers is impeded or suspended, thereby helping to put their relative contributions on an empirical basis. McGilchrist, for example, draws attention to the multiple ways in which persons with right-hemisphere damage show empirically significant deficiencies in the recognition of wholes rather than parts (McGilchrist 2009). For instance, such persons may rely on a particular kind of part to identify a particular kind of whole (such the identification of a house by its chimney), and produce drawings that show a loss of overall coherence and integrity (Hécaen and de Ajuriaguerra 1952; Nikolaenko 2004). Right-hemisphere lesions can also result in an inability to recognize faces (prosopagnosia), and faces being described in curiously “flat” terms (Sergent and Villemure 1989). Such damage may also be correlated with loss of appropriate moral responses to situations, especially those that are associated with the perspective of a second person (Tranel 1994; Tranel et al. 2002; Damasio 1994).

The significance of these findings to neurotheology is that many of the matters that are experienced in religious practice and studied by theology – including liturgy, the use of metaphors and narratives in sacred texts, the prioritization of the face in many kinds of religious art, what is personal, living, implicit, and unexpected – seem to be most closely associated with the “non-dominant,” right hemisphere of the brain. By contrast, the left hemisphere prioritizes the abstraction of things from their contexts, the representations of things in terms of previously

established types and classes, modeling and consequent prediction, manipulation and utility. Of course, such generalizations are subject to all manner of standard caveats and both hemispheres in practice contribute to a wide spectrum of cognitive processes. Moreover, the priority of the right hemisphere in the certain matters of religious practice and theology does not deny the distinctive theological contributions of the left hemisphere, including abstract reasoning, representational modeling, and contemporary analytic theology. The point being underlined by neuroscience, however, is that many of the matters experienced in religion and studied by theology remain irreducible to the abstract reasoning most commonly associated with the left hemisphere, having particular need of what is suited to right-hemispheric cognition.

For those desiring to preserve and pass on their faith, a possible implication is that narrative, metaphor, art, and music will be at least as important as clear and distinct ideas and arguments, an important corrective, for example, to iconoclastic tendencies every few centuries in Christian history. Yet the direction of causation is unlikely to be one-way. Matters of theology and religious practice are not only cognized by the right-hemisphere cognition, but plausibly shape such cognition, and not only of religious matters. This influence is perhaps most clearly illustrated in art. There is a great loss of a sense of religious transcendence between Van Eyck, *Adoration of the Mystic Lamb* (1432) and Van Gogh, *Wheatfield with Crows* (1890), but the perception of nature is also remarkably altered between these paintings, paving the way for the more radical developments of art in the twentieth century. Just as the right hemisphere was long dismissed as a "minor," "silent," or even an inferior "regressing" organ (Henschen 1926; Oldfield 1966), but is now recognized as playing a crucial role in the perception of wholes and contexts, so too the matters of theology have often been dismissed in recent centuries as contributing nothing of factual relevance to the study of nature, but such dismissals miss the point. The communication of theological matters shapes the perceived organization of the world by individuals and societies, one possible reason why different religious traditions often correlate closely with profoundly diverse societies. Hence, the widespread dissolution or alteration of theological narratives and images in a society may have surprisingly profound effects on the practice and priorities of many other branches of knowledge, even those devoted to strictly scientific and empirical matters.

A second key theme that emerges from neurotheology takes the form of a bifurcation that parallels, in certain ways, the issue of the divided brain. On one hand, a considerable amount of scholarship as well as much popular writing on the interrelation of neuroscience and theology focuses on the conceptual reduction of neurological processes to simpler and more tractable models, drawn either from more basic, nonhuman organisms or electromechanical systems. One might loosely describe this approach in McGilchrist's terms as a left-brain perspective on the brain itself. Such modeling is extraordinarily useful for many phenomena, but runs the well-known risk of what Dennett has termed a "greedy reductionism" that oversimplifies (Dennett 1995), rendering opaque and perhaps also sparking hostility toward whatever does not fit neatly within the model. An example in the history of

neuroscience generally might be early enthusiasm for modeling the brain as essentially a digital computer (Dreyfus 1992). An example of a similar reductive eagerness in neurotheology may be popular interpretations of the so-called God-helmet experiments developed by Stanley Koren and Michael Persinger, who reported that many subjects had “mystical experiences and altered states” while wearing the apparatus (Persinger et al. 2010). Regardless of the ongoing debates about these experiments, there seems little doubt that much public interest was rooted in the intriguing possibility that religious experience, and ultimately the entire superstructure of theological reasoning, might ultimately be reduced to feelings that can, in principle, be induced artificially in the brain.

Strongly reductive interpretations, popularly interpreted as “explaining away” theology and religion, are likely to continue to attract popular interest. Nevertheless, the chapters of this section may also show that neuroscience and theology can interact in a way that one might broadly describe as expansive rather than reductive. To draw on an influential example noted previously, it can sometimes seem that there is an “unholy alliance” between body-soul dualism in recent centuries and body-brain dualism or “crypto-Cartesianism” today. Contemporary neuroscience can, however, also help to foster a more integral understanding of human being and action in ways that may have surprising parallels with pre-Cartesian theological anthropology. For instance, the extent of the unconscious contributions to human action underlined by contemporary neuroscience is challenging to dualism. By contrast, there are parallels with the more integral anthropologies of medieval moral theology, for which the soul is the “form” of the body, with a vast array of “passions” (*passiones*) and established dispositions contributing to action.

Conclusion and Future Direction

Since neuroscience provides new and powerful means for exploring what it means to be an embodied human person, and since persons are central to revealed theology, a *prima facie* optimism about neurotheology seems appropriate. Despite the difficulties of demarcating the proper scope and methods of the field, certain consistent themes also seem to be emerging. In particular, whether at the basic level of religious experience or the selection and use of appropriate metaphors for subtle theological issues, an emerging theme is the special role of the non-dominant hemisphere. In addition, although strongly reductive interpretations that “explain away” theological matters are likely to attract ongoing popular interest, there are more expansive modes of interpretation. For example, the embodied cognition that is a central theme of modern neuroscience may have surprising parallels with a subtle, pre-Cartesian tradition of theological anthropology. Provided the challenge can be met of translating between theological anthropology and neuroscience without loss or distortion of meaning, the future seems promising for an enriched understanding of what it means to be an embodied human person open to theological revelation, giving new perspectives on human action and personal flourishing.

The Contribution of Neurological Disorders to an Understanding of Religious Experiences

97

Michael Trimble

Contents

Abstract

Following a brief introduction to epilepsy and the historical link to religious experiences, several studies carried out at the Institute of Neurology on the potential neuroanatomical basis of such phenomena are reviewed. It is concluded that epilepsy, particularly temporal lobe epilepsy, is linked to religiosity, and that the nondominant hemisphere is particularly involved. The data are discussed in the light of the growing interest in such disciplines as neurotheology and neuroaesthetics.

Introduction

The last two decades or so has seen the development of a new neuroscience discipline, namely, neurotheology. The emphasis of the subject is the unraveling of the cerebral basis of religious experiences, an endeavor initiated by William James over 100 years ago, and now promoted by new methods of brain imaging and by other techniques such as external stimulation the human brain with noninvasive techniques. However, the spirit of neurotheology is by no means new, and physicians have written about the subject in one way or another since ancient times. The condition most linked with these contributions has been epilepsy, and studies with this condition will be discussed in this chapter. After a brief introduction to the subject, the history of the associations between epilepsy and religiosity will be briefly reviewed. This will be followed by an account of some of the scientific work in this area, including studies from the Institute of Neurology, London.

The Epilepsies

Epilepsy implies a tendency to have seizures which are repeated, and which are not solely the result of exogenous influences. The term is used above in the plural to emphasize that there are many different epilepsy syndromes, and to note that epilepsy reflects underlying syndromes of which seizures are the main, but not by any means the only clinical feature. The epilepsies are divided into two main groups. In one, there are those patients who have a focus or lesion in the brain, which can be assumed from the clinical description of the seizure or detected either with an EEG, or some form of brain imaging. Patients from this group are referred to as having lesion-related or focal epilepsies. The other main group, the generalized epilepsies, has a different presentation, primary variants having no obvious brain lesions, and sometimes an obvious genetic basis. Establishing a site of origin of the seizures in the generalized epilepsies is problematic, and they are often assumed to arise from subcortical generators affecting both sides of the brain simultaneously.

Many patients with focal epilepsy have what are referred to as partial seizures, these arising secondarily to a change in the structure or the function of one or several brain areas. In one from, which arises from the temporal lobes of the brain, the seizures can be rather specific in presentation, and in the past, the term "temporal lobe epilepsy" was used to refer to this epilepsy syndrome. In the current classifications, this is referred to as a form of lesion-related epilepsy.

Temporal lobe epilepsy has some defining characteristics, which include a typical seizure pattern, with specific signs and symptoms, often an identifiable change of structure and function in one or both temporal lobes of the brain, and a tendency to be difficult to treat.

Patients with temporal lobe epilepsy seem more likely to suffer from secondary disabilities, referred to as comorbidities, which include behavior disorders and classifiable psychiatric syndromes. Thus, patients with this form of disorder have an increased liability to develop depression and schizophrenia-like disorders, and, in

a subgroup, a special form of personality change has been described. This is named after two neurologists who more clearly formulated the features, Henri Gastaut from France and Norman Geschwind from America (hence the synonym the Gastaut-Geschwind syndrome), although clear descriptions of this personality anlage can be found in the English and continental medical literature of the 19.c. (Gastaut 1956; Trimble 1991, 2007b). For reasons that are not always clear, these behavioral syndromes found in some patients with epilepsy have occasioned much controversy. This is not discussed here, but the point to be made is that these clinical pictures represent forms of an organic brain syndrome, namely, a behavior disorder that evolves from the continuing presence of chronic brain dysfunction. It needs to be emphasized at this point that only a minority of patients with epilepsy develop symptoms and signs of the Gastaut-Geschwind syndrome, and the full syndrome is not necessarily found in all patients. Some have only some of the features.

The Gastaut-Geschwind Syndrome

The characteristics of the Gastaut-Geschwind syndrome include such symptoms as alterations in sexual behaviors, irritability, and viscosity, the latter being a tendency to slow, labored thinking, as if thoughts are emerging from treacle. This sometimes is revealed as circumstantiality. However, two fascinating features of the Gastaut-Geschwind syndrome that are relevant for this contribution are hypergraphia and hyper-religiosity.

The former was first clearly described by Geschwind and his colleagues, and refers to the tendency to write excessively and often compulsively (Waxmann and Geschwind 1974). They initially discussed seven patients, all of whom were hypergraphic and all of who had temporal lobe epilepsy. The writings of these patients were extensive, and characteristically meticulous, and in four patients the written themes had moral and religious overtones. In a further paper, they published three additional cases; one of the patients was reported to have undergone multiple religious conversions. The writing revealed a preoccupation with detail, and a "compulsive quality to much of the written output." Repetition of words, and often sentences, was seen.

Since their publications, there have been several other studies of this interesting neurological sign in patients with epilepsy (Roberts et al. 1982). Some have been clinical; others have used some form of rating scale to assess the extent of the writing, and the feelings of a need to write. Some patients display hypergraphia more in association with their seizures (post-ictally); in others, it waxes and wanes over long periods of time. It is probably an all or nothing phenomenon, rather than some graded trait, and, as such, is easily missed in small groups of patients. However, the results tend to confirm the assertions of the original investigators, namely, that hypergraphia is associated with temporal lobe epilepsy, especially from a site of seizure focus from the medial (i.e., limbic), structures. The question of the relationship of laterality to hypergraphia is at present unclear, although at least one report noted an overrepresentation of right-sided foci. While the relationship of the hypergraphia noted in epilepsy to the ability to produce creative written

text for the moment must remain speculative, the phenomenon is obviously the opposite to the effects noted with left hemisphere lesions, with the subsequent development of aphasia and agraphia.

It has been noted that the content of the writing from patients with epilepsy with hypergraphia often reflects religious or mystical themes. Of 15 published cases, nine had hyper-religiosity or comparable extensive metaphysical beliefs, and those who see these patients regularly in the clinic, and who ask about such phenomena, recognize the frequent association with the metaphysical.

Religiosity

The association between epilepsy and religion has been one that stretches back to antiquity. Oswei Temkin, in his brilliant account of the history of epilepsy, noted several ancient historical religious explanations for the illness (Temkin 1971). Either a god had sent it or a devil was assumed to have entered the patient, or the attacker was thought to have sinned against Selene, the goddess of the moon. Superstition has always veiled epilepsy, the old name for epilepsy, "the sacred disease," even lingering on today in some parts of the world. While at some times and in some places, the patient with epilepsy was considered to be unclean, touched by evil forces, and contagious, at others, he or she was considered divine, magic, and able to utter prophetic oaths.

Descriptions of patients with epilepsy whose religious feelings have been notably strong can be found in the writings of several authors. The case of the religious mystic Emmanuel Swedenborg is often quoted. Swedenborg was born in 1688 into a deeply religious family, he studied at the University of Uppsala, being mainly interested in mathematics. In 1774, he changed his career and life and became involved with the spiritual world and its understanding. He discoursed with angels, became chronically paranoid suffering from hallucinations and delusions, ultimately declaiming that Jesus Christ had made his second coming through him to found the Church of the New Jerusalem.

Swedenborg lived a solitary existence, barely washing, obviously eccentric, but writing profusely. At one time, when he was in London, he proclaimed he was the Messiah, and locked himself away for 2 days, emerging from his self-imposed incarceration with foam around his mouth. His case was written up by the famous English psychiatrist Henry Maudsley (1869), who referred to him as a learned and ingenious madman. Maudsley suggested that he probably had epilepsy, a theme taken up later by Foote-Smith and Smith (1996). They interpreted many of the descriptions in his writings as symptoms of temporal lobe epilepsy, including his states of ecstasy, which would be compatible with ecstatic auras.

In addition to Swedenborg's religiosity however, these authors postulated more extensive elements of the Gastaut-Geschwind syndrome within his personality, not only with a deepening of all of his emotions, but also with regards to his hypermoralism, his humorless sobriety, his mood lability, and his hypergraphia. They pointed out that his *Arcana Coelestia* was a work of more than two million

words. Swedenborg himself claimed that spirits dictated much of what he wrote, and what the spirits were dictating came from God.

Toward the end of the nineteenth century, there was a considerable expansion of both the clinical and experimental neurosciences, and these historical associations, between epilepsy and religion, attracted the attention of psychopathologists with an interest in these matters. An analogy was developed between the epileptic attack and the moments of inspiration of genius, and interestingly in this context, pride of place was given to a number of famous geniuses who were said, on account of their inspirations to have suffered epilepsy. Dostoievsky himself alikened his states of ecstasy with the experiences of Mohammad, and he included people with epilepsy in several of his novels, notably the character of Prince Myshkin in The Idiot.

The whole topic of the relationship between epilepsy and religion has been reviewed several times (Trimble 1991; Saver and Rabin 1997; Trimble and Freeman 2006). Saver and Rabin list the following religious people of whom it has been said, at one time or another, that they had epilepsy: St Paul, Mahomet, Margery Kempe, Joan of Arc, St Catherine of Genoa, St Teresa of Avila, St Catherine dei Ricci, Emanuel Swedenborg, Ann Lee, Joseph Smith, Dostoievsky, Heiroymous Jaegen, Vincent van Gough, and St Thérèse of Lisieux. The majority were suggested to have had partial seizures, complex in form and compatible with temporal lobe epilepsy.

One of the earliest of as new generation of studies was that of Dewhurst and Beard (1970), who described six patients that underwent religious conversions, all of which occurred post-ictally after a series of temporal lobe seizures, essentially forming part of a post-ictal psychosis. Here is a description of one of the conversion experiences from their series:

The patient’s first conversion experience occurred in 1955 at the end of a week in which he had been unusually depressed. In the middle of collecting fares (he was a bus conductor), he was suddenly overcome with a feeling of bliss. He felt he was literally in heaven. On admission to hospital, he said that he had seen God and that his wife and his family would soon join him in heaven; his mood was elated, his thought disjointed, and he readily admitted to hearing music and voices. He remained in this state of exultation, hearing divine and angelic voices for 2 days.

Personality Changes

The Gastaut-Geschwind syndrome defines a change of personality in people with epilepsy, mostly associated with chronic temporal lobe epilepsy, in which one of the cardinal features is hyper-religiosity. With such predispositions, the state of a psychosis is not reached, but patients may adopt a divine, religious lifestyle, often contrary to their previous habits, but if already of a religious inclination, they reveal an accentuation of their previous rituals and beliefs. Their mental state however may flower into a psychosis with a bout of seizures, when they will report the most intense religious experiences. Sometimes they kindle a belief, over time, that they have epilepsy for a specific purpose, namely, that they are special and have

been chosen to suffer with it, and it is God's gift to them. This can sometimes be very dangerous, since they then may harbor the belief that God will cure them if He wants to, and that their antiepileptic drugs are unnecessary, which they then stop taking. This leads to more seizures and a deterioration of the psychosis.

It seems likely that if the clinical descriptions and biographies of several of the people already noted above have any validity, they illustrate the development of such chronic hyper-religious states over time, and several of the personalities discussed would today perhaps would be recognized as exemplars of the Gastaut-Geschwind syndrome.

Studies Carried Out at the Institute of Neurology

In recent years, The Raymond Way Research Group at the Institute of Neurology, Queens Square, London, has conducted several studies specifically examining aspects of religiosity and the often associated hypergraphia in patients with epilepsy. In one of the first, six cases of patients with temporal lobe epilepsy and hypergraphia were examined, and data collected and combined with those from 15 other published cases (Roberts et al. 1982). The patients wrote long, often detailed descriptions of their lives, and several were producing religious texts, such as the Bible or the Koran. Poetry writing was often a feature. There was often a meticulous attention to detail, and an associated mood disorder, mainly of euphoria, the latter was often linked to the hypergraphia. One patient, a journalist, was hypergraphic in the course of his work, but post-ictally, associated with a change of mood, he started writing in an entirely different style, and the content became philosophically bound, in complete contrast to his every day journalism. In the series, hyper-religiosity or comparable metaphysical beliefs were reported in nine cases, and seven had episodes of déjà vu. No patient had a left-sided focus for the epilepsy, and a statistically significant excess of right temporal abnormalities was noted. Déjà vu auras are usually driven by a right temporal lobe focus.

Here is a description of the full syndrome, described by Bear (1986):

A 56-year-old woman experienced a foul odor, followed by focal movements of the left face and arm, which on occasion generalized to a tonic-clonic convulsion. The surface EEG and recordings from indwelling electrodes implicated a right temporal lobe spike focus localized to the amygdala. The patient had composed thousands of pages of handwriting, distinguished by somber personal reflections, religious exegeses, and angry diatribes against former physicians, police, and politicians. Her writing was especially noteworthy, because she suffered painful, deforming rheumatoid arthritis, which required the use of finger and wrist supports. In her diaries, she commented "my hands are so sore but I have to just write." In addition to the unmistakable religious fervor of the writing, she traveled with satchels of audio-cassettes containing her own sermons on biblical themes.

In a more recent study at the Institute of Neurology, carried out with Anthony Freeman, the phenomenology of these states was investigated, especially the religiosity, in more detail, and has attempted a further understanding of the underlying brain associations (Trimble and Freeman 2006).

One problem is that measurement of such phenomena as religiosity and hypergraphia is difficult, with few available validated rating scales, and mainly a tradition of clinical observation to guide hypotheses. One scale used is that developed by Bear and Fedio, which was devised at the US National Institute of Health, precisely to fill in this gap. It consists of questions to assess 18 personality traits, many linked in the literature with the Gastaut-Geschwind syndrome (Bear 1986). One of the subscales relates to religiosity, another to hypergraphia. The scale comes in two versions, one for the patient to fill out, and the other for a carer or relative or person who knows the patient well.

In the original study of Bear and Fedio, the scoring on the religiosity subscale was greater in patients with temporal lobe epilepsy, even when compared to patients with mixed psychiatric disorders (and no epilepsy). However, there has been a controversy as to the specificity of the findings for the temporal lobe epilepsy, in part because of difficulties of studying patients with other forms of epilepsy, and excluding a temporal lobe focus. In the study to be described, the Bear-Fedio Scale was used, in addition to other scales that assess aspects of individual religious experiences and behavior. One scale was used, referred to here as INSPIRIT, and another, namely, the Hood Mysticism Scale. The INSPIRIT is a questionnaire that asks about spiritual or religious beliefs and experiences, including time spent on various religious practices, and how close people have felt to powerful forces of one kind or another. There are also direct questions about belief in God, and experiences that may have reinforced such beliefs. In our studies, this scale was modified to allow for a wider range of religious experiences to be documented than in the original and better descriptions of the nature of them. The Hood scale, which was based on Hood's readings of James's varieties of religious experiences, taps into the quality of them. There are two major factors evaluated by this scale, namely, general mystical experience and religious interpretation (Hood 1975).

Three experimental groups were defined. The first consisted of 28 people with temporal lobe epilepsy and a prominent devotion to religion – identified clinically. The second consisted of 22 people with temporal lobe epilepsy who had no religious affiliations, while in the third group were 30 regular church-goers, without known epilepsy. The purpose of the study was to examine in more detail the psychological profile of those patients with epilepsy and religiosity, and, by comparing them with the other epilepsy sample, to examine the underlying epilepsy variables that may be related to the religious experiences. By examining a group of non-epileptic worshipers, we hoped to capture phenomenological differences between them and our epilepsy sample.

The results of this study were very revealing. First of all, the original findings of Geschwind and his school were reconfirmed and the temporal lobe religious group not only as expected, endorsed the religiosity subscale of the Bear-Fedio scale, but they also revealed other elements of the Gastaut-Geschwind syndrome. Notably, the religious group also scored highly on the subscales of emotionality, philosophical interests, anger and sadness, dependence, and hypergraphia. They were also rated by a significant other to have more paranoia and mental viscosity than the non-religious sample. Thus, the profile that emerged in the religious patients with epilepsy was true to the original clinical descriptions of the Gastaut-Geschwind

syndrome, and emphasized hypergraphia, philosophical interests, and emotionality linked with the hyper-religiosity.

When the two groups of patients with temporal lobe epilepsy were compared, those with the religiosity were noted to more often have had a history of episodes of post-ictal psychosis, and more electroencephalogram changes that were bilateral compared to those without the religiosity.

The ordinary church-goers were different in their backgrounds from the epilepsy patients (more females, of an older age who were more likely to be married, and with a better educational level and occupational status), but they also differed in their religious behaviors. The patients with epilepsy and religiosity were more likely to belong to a religion not regarded as mainstream (i.e., Church of England, or Catholic); Seventh Day Adventism being popular. The question : "How often have you felt as though you were very close to a powerful spiritual force that seemed to lift you outside?," was endorsed more by those with epilepsy and religiosity than the non-epilepsy churchgoers, but interestingly, there was no significant difference in response to the question that asked if they had experienced any religious experience. Neither was there any difference in questions which asked about the frequency or duration of the religious experiences that they had.

The following statement from the INSPIRIT were endorsed more by the religious when compared to the non-religious epilepsy group:

How often have you felt as though you were very close to a powerful spiritual force that seemed to lift you outside yourself?

Items also endorsed more by the religious epilepsy sample were:

"an awareness of an evil presence";
"an experience of a miraculous event";
"a sensory or quasi-sensory experience of a great spiritual figure" or "an experience of a great spiritual figure" (such as Jesus, Mary, Elijah, Buddha or Allah);
"an experience with near-death or life after death";
"an experience of being punished in same way by God";
and "an overwhelming experience of fear".

On the Hood Mysticism Scale, the main features that identified the religious epilepsy sample were the "noetic," "temporal/spatial," and "ineffable" qualities of their experiences. Noetic here refers to the experience itself as a valid source of knowledge, with an emphasis on non-rational, intuitive, insightful experiences that none-the-less are recognized as not being purely subjective. Ineffability means the inability to express the experience in ordinary language, while the temporal/spatial dimension reflects on the experience as one in which time and space are modified.

The patients with bilateral temporal lobe electroencephalographic changes in particular scored higher on:

"the sense of presence of evil";
"an experience of a great spiritual figure";
"an experience of angels";
"a sensory or quasi-sensory experience of angels";
"a near death experience";
"an overwhelming fear";

"complete joy and ecstacy";
"being punished by God";
and "loss of self control".

These results lead to some relevant conclusions. Firstly, temporal lobe epilepsy can be associated with an identifiable constellation of behavioral dispositions, which have been identified for years, but are now better documented with rating scale assessments. This in its full form is referred to as the Gastaut-Geschwind syndrome. Secondly, patients with epilepsy and hyper-religiosity often have experienced post-ictal psychotic states, underscoring the potential links between their psychological profile and that of an epilepsy related psychosis. It is of interest in this context that states of hyper-religiosity are often seen in the context of such a psychosis (Kannemoto 2002).

With regard to the actual religious experiences, the epilepsy religious sample reported more experiences of the feeling of the presence of some external being, either of evil or of great spirituality, associated with feelings of death or dying and intense fear. The experiences are ineffable and noetic, not simply an awareness. There is identification, of and with that essence, and ecstasy and miracle are features of the descriptions.

Some caution must be given to the interpretation of the results of the above study, especially comparing church-goers without epilepsy with the religious patients with temporal lobe epilepsy, in part because of the demographic differences. However, from the neurological point of view, it was the patients with temporal lobe epilepsy and bilateral disturbances of function (as revealed through the electroencephalogram) in their temporal lobes who reported the most intense religious experiences, especially endorsing items to do with the inner subjective nature of their experiences, their ineffability, and the spatial/temporal component.

Other groups have also studied the links between epilepsy and religiosity. Csernansky et al. (1990) looked for correlations between psychopathological and neurological variables in a small sample of patients with epilepsy. They did not find a statistical difference with regard to laterality, but favored the left and bilateral abnormalities as opposed to the right hemisphere in association to the religiosity. Some others, also using rating scales, have not found such positive associations. These results have been reviewed elsewhere (Trimble 1991, 2007), but they do raise caution in interpreting these results.

MRI Studies

Of several hypotheses that have now evolved regarding the cerebral substrates of religious experiences, a role of the nondominant hemisphere and of some limbic lobe structures seem to have emerged as both testable and valid within the context of the growing understanding of brain structure and function, especially with regard to emotion. The above-reviewed literature seems biased toward a predominant role of the nondominant hemisphere, and studies in biological psychiatry have implicated this hemisphere as the one more associated with some affective disorders, namely, bipolar disorders and hypomania. Further, epilepsy has been shown to be

an interesting and reliable model of a neurological disorder associated with religiosity. It was with this background that the volumes of the hippocampus and the amygdala were measured using MRI in patients with epilepsy whose interictal behavior was rated using the Bear-Fedio Inventory (Wuerfel et al. 2004).

Thirty-three patients with refractory epilepsy were examined, and the volumes of the limbic structures were compared between those who scored high or low on three subscales of the Inventory, namely, "religiosity," "writing," and "sexuality." Patients who met the criteria for hyper-religiosity had significantly lower mean right hippocampal volumes than those not reported as religious. While in itself this finding was interesting, confirmation of the association emerged when the actual scores on religiosity were correlated with hippocampal size. Thus, there was a significant negative association between religiosity scores and hippocampal size, on the right side only. Further, this correlation was found for both patient self-ratings and on the independently obtained carer ratings – the smaller the right hippocampus, the greater the expressed religiosity. These data suggested that the right limbic structures may be of central importance to the development of these personality attributes, in keeping with the above developed hypothesis.

Other Neurological Disorders

Although it is the case that neurological conditions other than epilepsy are associated with states of religiosity, in reality they are few, and little discussed in the neurological literature. The best overall review is that of Saver and Rabin (1997). They point out that most religious experiences parallel similar non-religious ones, such as joy, love, fear, and awe, and that the emotions associated with the religious experience are ordinary emotions, differing little, if at all, in their emotional tone, but substantially differing in being directed toward a religious object.

They point out that the expressions of any particular religious language will depend upon the same mechanisms within the brain that relate to the expression of non-religious language, and conclude that the cerebral circuits underlying religious affect and cognition are not only widely distributed in the human brain but are a part of the cerebral apparatus available to everyone, the ecstatically religious and the non-religious alike. Thus, they opine that what is peculiarly distinctive to the religious experience is not so much to be found in the realm of affect, language, or cognition but in perception, namely, the direct sensory awareness of God or some other being. They, as William James, did not postulate an identifiable separate organ of religious perception, and in their paper, they attempt to understand the neurological substrates of such experiences as the direct awareness of a sacred or divine presence.

The above cited work on epilepsy has emphasized the links between temporal lobe-limbic structures and such experiences, and the personal descriptions of patients with epilepsy who are religious have revealed the intensity of these sensations. With regard to other neurological conditions, frontotemporal dementia (FTD) is almost the only other neurological condition discussed in the context of religiosity.

Frontotemporal Dementia

Dementia, which refers to a number of neuropathologies in which there is an acquired loss of intellectual abilities, has many causes, from the static, such as a head injury or injury to the brain from loss of oxygen, to the progressive. The latter dementias, sometimes referred to as parenchymatous dementias, usually arise in mid to late life, and present with a slowly progressive loss of skills and intellectual capacity, inevitably leading to dependency and death. The best known form is Alzheimer's disease, and a second common variety is dementia secondary to cerebrovascular disease. A third form, namely, frontal dementia, has been described for many years, and was referred to at one time as Pick's disease.

It has now become appreciated that frontal types of dementia are much commoner than previously thought, and the clinical and pathological pictures extend far beyond that condition described by the neuropathologist Pick. Thus, as a group, the FTDs tend to affect the frontal and temporal lobes of the brain and the presenting features are usually behavioral rather than cognitive in the first instance. The clinical picture will vary, depending on which parts of the brain are first affected by the pathology and on the rate of progression of the disease. In some patients, unilateral frontal or temporal lobe pathology occurs, and the temporal variant has been well described by Bruce Miller and his group from UCLA (Edwards-Lee et al. 1997). Hyper-religiosity is a feature:

Patient RTLV: A 59-year-old man, who made errors with calculations over 2 years, wore unmatched shoes and socks and tucked his jacket into his pants. Initially easygo-ing, he became stubborn and irritable. A religious awakening led him to spend hours in church; he argued with his wife and friends regarding his new religious ideas. His verbal output was fluent. A CT brain scan revealed mild atrophy, most marked in the right temporal lobe. A SPECT scan showed decreased cerebral blood flow in the anterior temporal regions, greater on the right. After he died, pathology was asymmetrically distributed, confirming the predominantly right temporal neuronal loss and gliosis.

In their summary of the clinical presentations, the authors commented that three out of five patients with the right-sided form of FTD had either increased religious ideas or heightened philosophical thinking.

A familial form of FTD was described by Lynch et al. (1994). Seven members of a family were identified with linkage to chromosome 17. The patients had person-ality and behavioral deterioration, in particular with signs of Parkinsonism, and initially release of abnormal behaviors, with disinhibition noted. Hyper-religiosity was noted in three. The behavior pattern was consistent with a frontal lobe dementia and, on pathological examination, all of the brains examined ($n = 6$) showed moderate to severe frontal and temporal lobe atrophy.

Saver and Rabin, in their discussion of the links between dementia and religious behaviors, make the point that in contrast to FTD, in Alzheimer's disease, along with the decline of many lifelong interests, religious concerns and practices also decline. They attempted to find a unified hypothesis of the neurology of religious experiences, largely relying on the epilepsy and dementia literature. They considered the primary substrate to be within the limbic system, and to be part of a distributed neural network marking events with either positive or negative valence. Acting as an intermediary between affects and cognitions, this cerebral system may mark experiences as either

depersonalized or derealized, as crucially important and self referent, as harmonious – indicative of a connection or unity between disparate elements, and as ecstatic – profoundly joyous.

This theory stands in contrast to, but alongside alternative hypotheses, which have emphasized the importance of the nondominant hemisphere in the modulation of holistic, nonverbal experiences, with the left hemisphere translating the experience of the nondominant hemisphere into an analytic and verbal version, which is inherently incomplete since the experience that is reported as in fact ineffable.

In the scheme of Savin and Raber, the perceptual and cognitive contents of the numinous experiences are seen as similar to those of ordinary mental experiences, but they are tagged by the limbic system as of profound importance united into a joyous unity. In their view, the descriptions of these experiences resemble those of ordinary experiences, but the distinctive feelings appended to them cannot be captured fully in words. They refer to "limbic markers," which can be named but cannot be communicated in their intensity, resulting in ineffability.

Disinhibition with social impropriety and offensive behavior are more a feature of the right temporal variant of FTD, and the authors concluded from their own observations that "the right hemisphere, at least the orbito-frontal and temporal aspects, may be necessary for mediation of socially appealing behaviour in humans." They go on to note, however, that since patients with epilepsy who have one or other of their temporal lobes removed at operation to help their epilepsy do not develop these severe behavioral syndromes, that the impaired behavior in their cases probably related to bilateral temporal lobe involvement.

Although their interpretation may be correct, that is about bilateral involvement, in keeping with the observations from the NHNN studies reported above, their observations about the effects of temporal lobectomy are not:

Patient TLE1: A female began to have seizures in her 20s. She had déjà vu auras, and then developed complex partial seizures and sometimes secondarily generalized attacks. Her EEG showed a right temporal lobe abnormality. She was mildly religious, but never went to church, and there was no psychiatric history before the operation, which was a right temporal lobectomy. The pathological study revealed amygdala and hippocampal sclerosis.

Immediately after her operation, the patient experienced the feeling of God's presence. She also had an auditory hallucination saying "its not time yet." She confessed that the experience was a revelation and that she believed that God was protecting her. She started attending church, often twice a week, and now goes to prayer meetings and meditation classes. She continues to feel the presence of God, and when strong, for example, in church, this is associated with feelings of euphoria and a racing pulse. She remains free of epileptic seizures.

Studies of Non-neurological Populations and Normals

These studies on patients with neurological disease are central to an unraveling of the neurobiology of religious experiences. Although the emerging behaviors can be

regarded as pathological, they have the same emotional tag and the same contents as those of the everyday experiences of millions of people who set about their religious observances in a socially appropriate fashion. It seems to be a fact that religious moments, inspirational and personally meaningful, are reported in a high percentage of normal people, perhaps up to 50 %. Most religious discourse relates to feelings about God or gods, and about beliefs in an afterlife or in reincarnation. In one survey in North America, 95 % of people confessed to a belief in God, and 71 % to a belief in the afterlife (Kroll and Sheehan 1989). However, in spite of the ubiquity of such sentiments in all social groups, there have been few studies that have addressed their potential neurological associations, or those of their behavioral counterparts, namely, the neural events and circuitry that may relate to behaviors of devotion.

Azari and her colleagues set out to test the hypothesis that religious experiences are not primarily emotional, that is related to a special feeling, the emotion in neurological terms being the feeling of the bodily responses as suggested by William James, but that they were cognitive-attributional (Aziri et al.). The areas of the brain activated by religious experiences induced in their volunteer subjects with religious recitation were cortical, especially the right dorsolateral prefrontal, the dorsomedial frontal, and the right medial parietal cortex (precuneus). No activation of the limbic structures was observed during the religious states, although in the happy state in the non-religious sample, the left amygdala was activated.

Although the states evoked in these volunteers are qualitatively different from those discussed in the neurological populations quoted above, the study is important in highlighting the cognitive components of religious states, and the role of the parietal cortex, especially of the nondominant hemisphere. The latter has direct connectivity with important structures in the limbic lobe, notably the parahippocampal gyrus and the cingulum, and as studies begin to unravel its function, the precuneus seems at least to be involved with autobiographical memory and states of self-awareness (Cavanna and Trimble 2006).

The work of Persinger and his collaborators, using volunteers and a special technique for stimulating the brain, covers two decades of scientific research into the links between the brain and religious experiences. He has also concerned himself with associations between symptoms and signs of temporal lobe disturbance and religiosity, and the role of the parietal cortex in such events (Persinger 2001). He notes that paranormal experiences are frequently associated with a sensed presence, involve the acquisition of information by a sense not regarded as normal, and contain distortions of time. Death or dissolution of the self are common themes, and embraced under the rubric "paranormal" are religious experiences, including sensing the presence of God, as well as other spiritual events such as haunts and alien abductions. Some of these experiences seem akin to those of the epilepsy patients discussed above. He refers to a continuum of "temporal lobe sensitivity" along which all human beings are distributed. Thus, using rating scales which measure temporal lobe experiences (temporal lobe sensitivity), his group reported that those individuals with the highest scores on

this scale also have more paranormal experiences, more frequent alpha rhythm over the temporal lobes on the EEG, and score higher on eccentric thinking and hypomania ratings using the Minnesota Multiphasic Personality Inventory, than those who score in the lower ranges for such temporal sensitivity. Using EEGs, he reported that temporal lobe transients (a wave of amplitude at least twice that of general activity – events he confusingly refers to as spikes) are significantly commoner in those with high temporal lobe sensitivity, and they correlated with religious belief or dogma clusters or "the feeling of presence" cluster on his measures.

Religious volunteers, as well as church attenders, score higher on temporal lobe symptomatology than the non-religious, and those reporting religious experiences were reported to be more likely to keep diaries, and enjoy poetry reading and writing (Persinger 1984a, b). All these data seem compatible with the epilepsy data reported above.

In another series of studies, Persinger stimulated the temporo-parietal regions of the brains of volunteers using very low frequency, weak magnetic fields, in the region of 1–5 μT in strength. This evoked in most normal people a feeling of a sensed presence, but the latter was more often elicited from those who had elevated scores on the measures of temporal lobe sensitivity. Interestingly, they were evoked most easily when applied for a period of 20 min after which "…a bilateral burst-firing pattern …was applied over the temporal poles for an additional 20 min" (Persinger 2001). While Persinger's results bear consideration, they also require much caution, not the least problem being their lack of replication by others. His equating of temporal lobe EEG changes in normal people with the underlying processes of epilepsy is highly questionable, as are some of his neurophysiological arguments. The neurophysiology is simply not that well worked out, and while the ability of microtesla stimulation of the brain to evoke paranormal experiences remains an intriguing observation, this does require independent verification.

However, his conclusion that religious experiences are evoked in normal brains by small electrical events in temporal lobe structures, that the parietal lobes are relevant to these experiences, and that bilaterality of stimulation may be a required feature of the response again is in keeping with the hypotheses which are emerging from the epilepsy studies.

Neurotheology

Neurotheology is a branch of neuroscience which has barely developed in recent years. However, there are now established University Departments that study the science of religion, and neuroscientists have taken up the challenge to investigate not only consciousness in its broadest context, but also emotional states, including those associated with religious feelings and practices. Neurotheology stands alongside other topics such as neuroaesthetics, as valid areas of neuroscience that can now be explored with, for example, brain stimulation and brain

imaging techniques. They represent neuroscience offshoots of what the biologist E O Wilson called sociobiology, namely, the systematic study of the biological basis of all forms of social behaviors, across the phylogeny, and including mankind. For him, religion was one such behavior which was universal, conferred genetic advantage, and, indeed helped drive evolutionary change (Wilson 1978).

This contribution reveals that there are, in reality, very few neurological disorders other than epilepsy that are associated with hyper-religiosity. The main one is FTD, and, taken with the epilepsy studies, the burden of the evidence favors bilateral limbic involvement but with an emphasis on changes in the right, nondominant hemisphere. The case cited above in this chapter also notes that removal of the right temporal lobe can release religious ideation and behaviors. This fact alone, plus the phenomenology of the described states, with the strong sense of presence of another in extracorporeal space, which is such a common denominator of patient experiences, implies involvement of other cerebral structures in such phenomena, and several authors have drawn attention to parietal lobe involvement. The volunteer studies strongly support this interpretation, especially the data from Azari and her colleagues and Persinger's group. The relationships of the parietal cortex to the body image, to the sense of self, and to states of self-consciousness require further studies, but they seem related to a circuitry which allows for the emergence of intense emotional religious experiences, bound with the activity of the limbic paleocortex. The dominance of sensory experiences, the predominance (but not exclusive) activation of the nondominant hemisphere, and the role of structures such as the precuneus, all help to explain the numinous, ineffable yet incorporated nature of religious epiphanies.

The forces of natural selection that shape our behaviors are discussed by nearly all contributors to this field. Mankind is, from an evolutionary point of view, young, but the human brain derives from eons of selective pressures. The genetic contributions to our behaviors, including religious behaviors, simply cannot be ignored. Indeed, there are several studies of the genetics of religiosity, the most convincing being that of identical twins reared apart, where the environmental influences on their behaviors will be different. Monozygotic twins, with ostensibly the same genetic apparatus, have been compared with dizygous twins, reared apart, on a variety of rating scales of religious beliefs and behaviors. It has been shown that monozygotic twins are more alike than dizygotic ones, and it has been calculated that some 50 % of the observed variance in religious experiences and beliefs is genetically rather than environmentally influenced (Waller et al. 1990). The molecular biologist Hamer (2004) has published his *book The God Gene*: *How Faith is Hardwired into Our Genes*, in which he claims not only that spirituality is adaptive from an evolutionary point of view, but that the gene(s) related to it are linked to those which regulate the neurotransmitters that control mood. There is no God-spot, as some lay commentators have naively tried to tie down some neuroscientists to claim, but *Homo sapiens* does bear the legacy of millions of years of mammalian neuronal tissue that has driven succeeding generations to thrive and

survive. The sapiens has arrived very late, but has arisen only upon development of the neurological substrates of our ancestors, revealing to us chthonic embedded behavioral patterns of the past. Religious experiences can only be interpreted in such a context, unless the discoveries of the last few hundred years of evolutionary biology and neuroscience are to be ignored.

Conclusions and Future Directions

Neuroscience, as a scientific discipline, must adopt a neutral stance to any investigations and subsequent results carried out in the area of brain and behavior, irrespective of the subject matter, and religious experiences and behaviors cannot be immune from such enquiries. At present, there are few hard and fast data to call upon in the area of neurotheology, and most of the writers recycle the same results from a small number of disparate investigators. In a recent review of the neuroscience of religious experience, McNamara (2009) sums up the anatomical findings as follows: "in summary, the circuit that mediates religiousness involves primarily limbic, temporal and frontal cortices on the right," (p. 129). Evidence is slowly accumulating, at least for some understanding of the cerebral associations of religious experiences. They are embodied, in the brain, and the key circuits involve the limbic circuitry and its associated pathways including the parietal lobes of, at least, the nondominant hemisphere. Future work will either support or refute these findings, but neurotheology, like its related discipline neuroaesthetics, will increase its field of influence over the next decade:

> Know then thyself, presume not God to scan,
> The proper study of mankind is man.[1]

Cognition, Brain, and Religious Experience: A Critical Analysis

Contents

Abstract

This chapter presents critical perspectives to neurotheology particularly in the light of cognitive science and philosophy. The main arguments revolve around the notion of "religious experience" and its usefulness in explaining religious phenomena. After providing a brief overview of the various forms of neurotheology and cognitive science of religion, it is argued that the study of religious experience might not be the best available starting point for the study of religion in general. This is mainly because the types of strong religious experiences that many neurotheologians study are unlikely to explain the prevalence of religious concepts and practices in general. The chapter also examines some more philosophical worries related to neurotheology. The main problem is the tendency to see the brain as the central explanatory factor of all our experiences and subsequent neglect of other levels of explanation (cognitive, everyday psychology). The final section highlights some of the positive

contributions that neurotheology might make to the cognitive science of religion. These include focusing on the role of emotions in religious thinking and possibly challenging the deeply entrenched computational theory of mind in the cognitive science of religion.

Introduction

This chapter provides some critical perspectives to neurotheology particularly in the light of cognitive science and philosophy. The main issues revolve around the notion of "religious experience" and its usefulness in explaining religious phenomena. The chapter begins by looking very briefly at what kind of activities go under the headings of neurotheology and the cognitive science of religion. These preliminaries set the scene for the next part in which the different views of the centrality of religious experience in NT and cognitive science of religion are discussed. The third section addresses some general philosophical worries that have to do with NT. The final section highlights some of the positive contributions that NT might make to the cognitive science of religion.

Neurotheology and the Cognitive Science of Religion

The term "neurotheology" (NT) is somewhat vague, and it is unclear what kinds of activities it refers to. Normally, it has been used to refer to the neuroscientific studies of religious experiences, such the work of Andrew Newberg, Eugene D'Aquili, Michael Persinger, and several others, but there are at least two further kinds of research that could be considered as NT making three categories in total:

1. Neurotheology as the neuroscientific study of religious and spiritual experiences. Let us call this *neurotheology in the narrowest sense*.
2. Neurotheology as an activity in which neuroscientific results or data about the workings of the brain is religiously or theologically reflected and discussed. We can call this *neurotheology in a theological sense*.
3. Finally, neurotheology as a general program for scientific, religious, and theological study, as envisioned by Andrew Newberg (2010) and others. For them, neurotheology is a field of research combining science, religion, and theology in order to answer both scientific and religious questions. Newberg and some others (e.g., essays in Joseph 2003; Beauregard and O'Leary 2007) also draw religious conclusions from their research. Let us call this *neurotheology in the programmatic sense*.

NT understood in the narrow sense – as the neuroscientific study of religious and spiritual experiences – is strictly a scientific enterprise. The neuroscientist might be interested in studying, say, the experience of pain in connection with religious motivations or experiences, emotions linked to religious rituals or even altered states of consciousness apparent in some meditation practices just to mention a few topics. NT in a theological sense refers to theological or religious reflection of

neuroscientific results. Here the methods and assumptions are primarily theological, religious, or spiritual conceived in a broad sense rather than scientific (e.g., Watts 2002; Russell et al. 1999; Jeeves and Brown 2009). Oftentimes these two enterprises go together, especially when neuroscientists derive religious (or non-religious or anti-religious) conclusions from their results (e.g., Beauregard and O'Leary 2007).

The third referent for "neurotheology" is the proposed research program that attempts to include NT both in narrow and theological senses and expand their influence. According to Andrew Newberg, one of the architects of this program, "neurotheology refers to the field of study linking the neurosciences with religion and theology" (2010, p. 45). He goes on to emphasize that NT is not simply a scientific or religious enterprise but both, "Most importantly, neurotheology should be considered a two-way street with information flowing both from the neurosciences to the religious perspective as well as from a theological perspective to the neurosciences so that ultimately, both perspectives will potentially be augmented by the dialogue" (2010, p. 45). In its programmatic sense, NT constitutes an attempt to create a field of research in which scientists, theologians, and religious (and non-religious) people in general can reflect on the nature of religious phenomena and their relationship to our minds and brains. Newberg sees neuroscience in a very broad way as including cognitive neuroscience, psychiatry, psychology, and even social sciences such as sociology and anthropology.

Although NT in its programmatic sense seeks to encompass almost all scientific study of religion as well as its religious reflection, each activity can be distinguished from the others in terms of the goals of the people involved. The goal of the first type of activity is to produce scientific theories about the workings of the brain and how they contribute to (or correlate with) religious experiences. Bringing neuroscience to bear on religious phenomena might go further than just religious experience as, for example, in the work of Patrick McNamara (2009). Nevertheless, such pursuits are purely scientific activities and do not entail any explicit theological or (anti-)religious agenda (or at least it should not include such an agenda). In the second type of NT, the goal is the generation of some theological or more broadly speaking religious set of ideas that incorporates (or rejects) the scientific theories about religious experience and the brain. Here we have an activity that is best characterized as motivated and shaped by religious or philosophical rather than scientific interests.

Finally, there is NT in its programmatic sense that seeks to form a field that will supposedly have good scientific and religious effects. The ultimate goal of such a field would be a kind of Grand Unified Theory that combines both scientific theories and various religious and theological views about religious experiences and their relationship to our brains. Newberg calls this *megatheology* (e.g., Newberg 2010, pp. 64–65; D'Aquili and Newberg 1999, pp. 195–203). Such a megatheology would be a theology that potentially all religious people could accept and it would consist of neuroscientific explanations of mystical religious experiences and the more religious defense of their validity and usefulness.

Megatheology would be, if not orthodox in the traditional religious sense, at least more or less affirming the goods of spiritual or religious life. In what follows, when NT is referred to, the main meaning will be NT in the programmatic sense described here.

Compared to NT in its programmatic sense, *the cognitive science of religion* (henceforth, CSR) is a much more modest and narrowly defined enterprise. What the cognitive scientists of religion seek to do is to explain the cross-cultural recurrence of certain ideas and behaviors. Such behaviors and ideas include different kinds of rituals, beliefs about supernatural agents such as ghosts, spirits and gods, myths and divinely sanctioned morality. Instead of focusing on religious experience as a source of religion, the CSR looks at the cognitive underpinnings of religious thinking and behavior, namely, tendencies in human information processing that, given many kinds of cultural transmission events, create recurrent patterns. The central assumption here is that the human mind has some more or less natural information-processing tendencies and biases that are independent from specific cultural traditions. These tendencies and biases make some types of ideas easier to acquire, remember, and transmit than others. The prevalence of religious ideas suggests that they are particularly easy to adopt and transmit. In time, we would expect such ideas to become widely transmitted and shared, that is, to be incorporated into the prevailing culture. Several different lines of research provide evidence for this claim. Pascal Boyer and others (Boyer 1994, 2002) have argued that ideas that closely approximate our *intuitive assumptions* about the characteristics and causal properties of things in the world are easily acquired, remembered, and transmitted, compared to ideas that are *highly counterintuitive*, that is, ideas that require extensive learning and reflection. Boyer's claim is that religious ideas strike a balance between intuitive ideas and highly counterintuitive ideas and are, thus, attention-grabbing and memorable. Further, the greater the inferential potential of an idea, the more memorable it is. Inferential potential is understood here as an ability of an idea to generate inferences, predictions, and explanations pertinent to widely recurrent human concerns. Ideas about non-mundane agents (say, invisible spirits or ancestors) are both minimally counterintuitive (spirits are like humans but invisible) and have inferential potential (relevant for morality, misfortune, etc.).

Boyer's account has been supplemented by other theories that include a similar notion of cognitive naturalness. Scott Atran (2002) focuses more on the role of religious rituals as signals of commitment. Justin Barrett (2012) has argued that many religious ideas have a natural cognitive foundation that is manifested very early in human development. Developmental studies suggest, for instance, that children have a tendency to see many features of the natural world as designed or having a purpose and that this tendency is so strong it must be consciously overridden or else will persist into adulthood (Kelemen 2004). Such a tendency would make the notion of an intentional agent being behind the design of nature very natural. Further, some results suggest that certain divine attributes, such as "superknowledge" (having access to all relevant information about a particular situation) and immortality, are also natural for children, because children actually

understand all agents (not just gods) in these terms. Beings with minds are assumed to have complete knowledge, for example, until children learn otherwise. Finally, there are studies suggesting that belief in souls and afterlife are natural in the sense that they are supported by intuitions about minds, bodies, and death (Bering 2006; Bloom 2007).

The central argument of the CSR is, therefore, that religious ideas and behaviors are *natural* to beings with minds like ours. In order to avoid confusion, we need to explicate the technical notion of "naturalness" being employed here. As we have seen, "naturalness" refers to a certain kind of cognitive ease, but this comes in different varieties. Robert McCauley (2011) usefully distinguishes *maturational naturalness* from *practiced naturalness*. Practiced naturalness characterizes activities that require conscious training and cultural scaffolding. Riding a bike, driving a car, and writing are prime examples of practiced naturalness: When performed, they are automatic and easy, but they had to be learned through conscious effort and instruction. Maturationally natural activities, such as learning to speak one's native language and acquiring a set of basic moral feelings, are characterized by the same ease and automaticity but they arise without explicit instruction or learning. As a consequence, they seldom require special artifacts or teachers and emerge early in childhood. The main argument of CSR is at least some core cognitive processes associated with religious thought and behavior are maturationally natural. Compared with, say, science, chess, literacy, or bicycle riding, beliefs about gods and their moral nature, design in nature, and souls surviving death are largely natural in the maturational sense.

Religious Experience in Neurotheology and Cognitive Science

The category of "religious experience" has been notoriously difficult to define. In both philosophy and the study of religion, several different definitions have been offered, but no consensus has formed (Taves 2011). For the purposes of this chapter, it is enough to make a very rough distinction between religious experiences in a narrow sense and a broad sense. Religious experiences in the narrow sense refer here to experiences that are strongly non-mundane, that is, involve strong emotions and differ markedly from the experience of everyday life. Sudden visions, trance-like states, and other "altered states of consciousness" would qualify. William James' *Varieties of Religious Experience* (1985) is still a good source of vivid descriptions of experiences of this kind. Religious experiences more broadly construed can involve more mundane and long-term phenomena like the continuous feeling of God being present, and need not involve intense, punctual emotional arousal.

In terms of background, there is the debate between *perennialists* and *constructivists* about religious experiences (Taves 2011). For the perennialist, there is a shared, non-conceptual, or non-linguistic core to most religious experiences. Although some content and form of religious experiences depends on surrounding cultures and concepts, the core is independent from them. This core is usually understood in terms of pure experience or "pure consciousness." Against this, the

constructivist argues that there is no such thing as “pure experience” or consciousness, but instead all experience is mediated by concepts and language, which are in turn shaped by the surrounding culture. The debate is mainly about the correct approach to the study of religious experience: Should we explain what religious concepts look like with what religious experiences feel like or should we instead explain what religious experiences feel like in terms of religious concepts?

At first sight, the representative of the CSR would side with the constructivist and maintain that when we have explained the concepts and representations that are involved in religious experience, we have in fact explained the experience itself. Very roughly, the basic workings of the human mind explain why our concepts are what they are and they, in turn, shape our experiences. The representative of NT would be closer to the perennialist and maintain that there is an experiential core to religious experience that is not explainable in terms of cognition, information processing, and the cultural and linguistic context. In other words, there are some fundamental and cross-cultural truths about what, for example, unitary states of consciousness feel like and their explanation goes beyond explaining the concepts involved in describing the experience. For the neurotheologian, very roughly, the brain explains why our experiences have the characteristics that they do and the experiences, in turn, explain why we have the concepts that we do.

It seems fair to say that most of the work in NT has so far focused on the experiential and emotional aspects of religion. To be more specific, the main theories have to with “experiences of God” or some other type of “spiritual realities” and the practices that evoke these experiences (e.g., ritual, praying, meditation). For example, Michael Persinger (1987, 2003) has suggested that the “experience of God” is associated with deep microseizures in the temporal lobes. When Persinger stimulated magnetically certain parts of the temporal lobes, several subjects reported sensing “a presence of a sentient being.” The experiences were reported as making every aspect of the world feel profoundly meaningful, having a sense of unity, and being at peace with the world. Further, it might be the case that such “God experiences” can be triggered naturally by stress, anxiety, or by environmental conditioning linking the experiences to religious contexts. On the basis of the fact that when taken to the extreme, microseizures in the temporal lobes are connected with temporal lobe epilepsy (that manifests itself as psychic seizures without bodily convulsions), Persinger suggests that there is a connection between “mystical experiences” and temporal lobe epilepsy or other similar malfunctions. Ramachandran and others (Ramachandran and Blakeslee 1998) have also studied the connection between the temporal lobe and mystical experience by looking at persons with temporal lobe malfunctions or epilepsy. Their conclusion is that there is no clear evidence for religious stimuli being processed in the temporal lobe only. This suggests a more modest conclusion than that of Persinger’s. It is likely that there are some specific brain functions linked to religious experiences and that temporal lobe epilepsy sometimes involves intense “religious” experiences, but there is no clear connection between mystical experiences and the temporal lobe.

Another well-known NT theory is that of Eugene D'Aquili and Andrew Newberg (1999, 2002). Based on numerous brain-imaging studies of meditating or praying subjects, D'Aquili and Newberg claim that there is a hard-wired core experience they call *Absolute Unitary Being* (AUB). In the AUB state, "the subject loses awareness of discrete limited being and of the passage of time, and even experiences an obliteration of the self-other dichotomy" (1999, pp. 109–110). Unlike Persinger, D'Aquili and Newberg do not refer to any kind of brain pathologies here; for them, the AUB state is a product of a normally working brain in very specific circumstances. The neurobiological mechanisms undergirding these experiences are the sympathetic and parasympathetic nervous systems which rituals and prayers stimulate (for criticism, see, e.g., Atran 2003).

Now, the question is whether focusing on the neural correlates of religious experiences is fruitful for the study of religion. Newberg and other representatives of NT seem to think so. Contrary to this, cognitive scientists in general and the representatives of the CSR in particular usually think that focusing on religious experience (narrowly or broadly defined) is not very fruitful when explaining religion. There are several reasons for this.

First of all, most representatives of the CSR want to reject most traditional theories of religion in which religion is understood as having a specific essence or inner nature. Such theories of religion have often postulated a *sui generis* religious experience of, for example, the Holy (Rudolf Otto) or the Sacred (Mircea Eliade) as the core of religion. Since this experience and its object are *sui generis*, in a category of their own, the core of religion cannot be accessed outside the experience of the Holy or the Sacred. Such a view implies that there is a special "religious cognition" or some other psychological mechanism that is specific to religion. This is also what NT, at least partly, suggests: There are experiences that are unique to religion, and they have unique patterns of brain activation.

Against this view, the cognitive scientists maintain that there is neither a *sui generis* essence to religion or religious experience nor uniquely religious cognition (e.g., Boyer 1994). Instead, religion is considered to be a vague and diverse collection of different kinds of phenomena, such as rituals, stories, myths, moral feelings, and reasoning about supernatural agents and their powers. We need not assume, so the argument goes, that there is some unifying essence to all these phenomena. Instead, what we have is a collection of different kinds of thoughts and practices that utilize various non-religious cognitive mechanisms. Thus, we explain ritual in terms of our non-religious ways of representing actions or beliefs about souls and afterlife in terms of our non-religious intuitions about minds and bodies.

Another reason for the rejection of religious experience as an interesting topic of study is that the category of "experience" does not really function as an explanatory factor in cognitive science. This is because descriptions of experiences involve phenomenological notions and concepts, that is, concepts that describe what things "look like" to the person who is the subject of some particular experience. For the classical computationalist and functionalist paradigm of cognitive science, however, there are no such things as appearances or "seemings" in the workings of

the mind. The mind is (or can be treated as) a kind of computer transforming symbols. In other words, everything that the mind does can be explained in terms of computation of symbolic representations. Representations are, ultimately, coded in the brain in some form or another, and they involve nothing like "seemings" or "experiences." This view is often coupled with a view of *emotions* as highly specific programs that are designed by natural selection to produce certain kinds of behaviors (e.g., aversion, self-preservation). On this view, emotions are not defined or explained in terms of what they "feel" like, that is, what their phenomenal qualities are, but instead in terms of the informational input and resulting behavior. This approach is again typical of the computational/functionalist approach to the mind. The view amounts to a kind of "no experience" theory of the mind – would bracket out phenomenological notions, like "seemings" and feelings, as explanatory factors. Because of the prevalence of the computational/functionalist paradigm, in most (especially pre-2002) CSR work (e.g., Sperber 1996; Boyer 1994), "experience" of a religious subject is simply seen as the subject having certain kinds of beliefs. So having a religious experience is nothing more than having religious-type beliefs about the sources and causes of the events of one's surroundings.

More recently, some representatives of the CSR have tried to expand the theoretical resources of the CSR beyond this "no experience" view of early CSR and computational cognitive science. Ilkka Pyysiäinen has argued that religious experiences are more than simply beliefs: They involve emotions and evaluative judgments that guide actions (2001a, b). Pyysiäinen's theory of religious emotions draws directly from neuroscience and the work of Antonio Damasio (1996, 1999) and Joseph LeDoux (1996) in particular. Scott Atran (2002) has also argued that pure cognitive theories of religion are not enough and more attention should be directed to how religious beliefs and practices manage both positive and negative emotions in situations of "existential anxiety." Finally, the *Modes of Religion* theory of Harvey Whitehouse (2004) includes an explanation of the links between different kinds of rituals and their emotional intensity. Given these developments, it would be unfair to say that the CSR simply neglects the emotional or the volitional aspect of religion. Nevertheless, these theories are "cognitive" in the sense that they see religious experience in terms of information processing, not in terms of what these experiences feel like or what their neurobiological correlates are. Religious experiences are, very roughly, non-ordinary experiences interpreted in terms of religious concepts that elucidate strong emotions. This might be the place where NT has something to contribute to the CSR. I will return to this topic in the last section.

Finally, the third reason for rejecting religious experience as an explanation of religious phenomena has been the relative rarity of intense religious experiences like unitary or trance-like states. Again, nineteenth century psychologists of religion, such as William James, thought that religions stem from the experiences of sages and seers or "religious geniuses" like Jesus or Buddha. The great masses would then simply be impressed by the experiences of the geniuses and follow their insights. That James thought along these lines is unsurprising, since the romantic focus on the emotion and the heroic individual was the trend of the age.

The criticism later directed against such theories was that they are impotent in explaining the prevalence of religious behavior and the recurrent patterns in religious traditions. This is because religious experiences of the narrow kind exhibited by the "geniuses" are so rare.

Scott Atran (2003, p. 165) writes that "even if neurotheological speculations about the biological correlates of mystical experiences were true, there is no evidence that less extreme, more "routine," religious experiences have some characteristic brain-activation pattern." Atran then refers to a poll according to which approximately one third or one fourth of American and British subjects report having a religious experience, but only 2–3 % report having an intense "mystical" experience, such as feeling everything being one. So even if we are generous, the kinds of mystical experiences that representatives of NT such as Newberg and D'Aquili theorize about are quite rare among the religious. So to explain religion, it is not enough to explain the intense experiences of some "religious geniuses," because that would leave us without an explanation as to why religious people that have no such experiences (most religious believers) actually believe and understand what the geniuses are saying. Instead, what we need to explain is why people are ready to believe that non-mundane experiences have something to do with special realities, gods, spirits, and the like. In other words, why are people disposed to explain strange experiences in religious terms. Such an explanation, the argument concludes, needs something much more than just a neuroscientific explanation of narrowly defined religious experience. As Atran puts it, "mystical episodes may inspire new religions, but they do not make religion."

Atran summarizes the critique from cognitive science well, "despite intriguing findings concerning neurobiological correlates for certain types of intense religious experience, broader neurotheological interpretations of the findings are unwarranted. They involve speculation that not only strays way beyond the facts but crucially ignores or contradicts much recent work in cognitive and developmental psychology and cognitive anthropology" (2003, p. 165).

Additional Critical Perspectives

Representatives of NT often seem to think (or at least imply) that the constitution and workings of the brain are the only possible explanations of human behavior and thinking. It is rather typical of many representatives of NT to argue in the following way. Newberg and D'Aquili (1999, p. 45) write that "no matter what happens to us or what we do, there is a part of the brain that becomes activated. – Thus, the brain appears not only to react to everything that happens to us, but is eminently responsible for everything that we do or experience. In this way, studies of brain function help to show that . . . it is the brain by which all of our thoughts, feelings, and experiences are derived." The suggestion here seems to be that since all of our thoughts and behaviors involve brain events, they are best explained in terms of brain events. But this does not follow. Let us call this the "fallacy of micro-reduction."

The point can be made best by distinguishing singular causal explanations from *constitutional* explanations. We might wonder why a vase is broken on the floor in a pool of water. A singular causal explanation would give us the cause of this vase falling down from the table and breaking. One relevant explanation might be the strong wind that blew in from the open window. A constitutional explanation would answer a slightly different question, namely, why did the vase fell to the floor and broke instead of, say, flying up and staying in one piece. Now, the explanation would be given in terms of the physical structure of the vase and the floor and the general physical laws that govern their behavior. The point of this distinction is that the physical constitution of the thing being explained or the physical mechanism that produces the effect were explained is not necessarily the correct level of explanation. In other words, even if it the case that our thoughts are physical operations in our brains and that all our actions are, therefore, causally mediated by brain functions, it would not follow that all explanations of our thoughts and behaviors should be given in terms of what goes on at the micro-level of our brain (Craver 2007). Similarly, explanations in, say, biology and chemistry need not be given in terms of physics even though basic physical events and processes constituted all biological and chemical events and processes.

Atran (2002) coined the term "leapfrogging the mind" to pinpoint what he sees as the main problem of evolutionary explanations of human behavior. His argument is, very roughly, that when explaining what humans do, we have to explain how they believe and represent the world. Whatever biological or evolutionary causes human behavior might have, they have to be mediated through human cognitive systems. It is valid to look for an evolutionary explanation for some specific behavioral trait, but the explanation should not stop there. We also need an account of how evolutionary causes actually cause the behavior of humans in terms of the functioning of their cognitive system. So evolutionary explanations tend to skip an analytic level, that is, they leapfrog the mind and jump go straight from the evolutionary function of the behavior to contemporary human behavior without considering how human psychology works. The same kind of leapfrogging seems to be at work in NT in its programmatic form, in which the level that is skipped is the cognitive, the level of information processing. Behavior and thinking (the level of commonsense description) is explained by brain functioning (the level of neuroscience) without an account of the cognitive processes that mediate these levels.

The lesson here is that different levels of analysis need to be kept separate (at least at first). In our case, the relevant levels of analysis would be (1) the neurochemical and physiological mechanisms of the brain, (2) the information-processing mechanism of the mind, and (3) the everyday description of mental events, including descriptions of religious experiences and such. So even if there were some brain activation or a mechanism associated with everything we think and do, that does not mean that we could explain (or even should try to explain) all our behavior and thinking in terms of what happens in the brain.

There is a further point to be made about jumping or skipping levels. Cognitive theories of religious thinking suggest that religious thoughts are processed by cognitive mechanisms that also process non-religious thoughts. If this is true, when people

are reasoning about the intentions of God, gods, or spirits, they are using the same cognitive machinery that produces beliefs about the intentions ordinary, mundane human beings. Similarly, the same systems that we use to represent actions are used to make sense of religious ritual actions. This is simply a consequence of the more general point of the CSR maintaining that there is no "religious" cognition. If true, the prediction would be that on the level of brain function, there is nothing to distinguish ordinary religious thinking from ordinary non-religious thinking. On the level of neuroscience, therefore, there should be no difference between thinking about quantum mechanics, the nature of God as the First Cause, or the warrant for Darwinian notion of species. So no matter how hard we look at the ordinary religious brain that is not in a state of intense religious experience, we are unlikely to see anything that would distinguish it from a non-religious brain. Notice that what is being argued here is *not* that NT can explain nothing interesting or relevant about our experiences, behavior, or thought. Instead, the argument is simply that the neuroscientific level of analysis in which NT operates is not necessarily the best level of analysis in most cases of religious thinking and behavior.

Neuroscience in general and NT studies in particular often suffer from a problem that somewhat resembles the issue of micro-reduction and level skipping. At least on the surface level, neurotheological texts are rife with talk in which all sorts of activities are attributed to the brain. Brains, we are told, think, perceive, and have trance-like states and absolute unitary experiences. Not only does the brain "experience" the world, but different parts of the brain might "have different experiences" or "perceive the world in different ways." This may all be just a sloppy use of language, but the prevalence of the talk is indicative of a view according to which the human brain is the agent of human action. This, of course, would fit in very well with the micro-reduction that was just mentioned. If the brain is the cause of human actions and thoughts, it is the brain that is the agent of human behavior, not the person herself. The "person" or the "self" is only a construct of the brain, not the cause or the subject of actions and thoughts.

As with micro-reduction, there is a problem here. In their book *The Philosophical Foundations of Neuroscience* (2003), Maxwell Bennett and Peter Hacker argue that it is a mistake to attribute the properties of the whole to the parts of the whole. They call this the *mereological fallacy*. Let us consider the act of writing an essay on a laptop. It is not the computer motherboard or the processor alone that does the word processing, but the whole computer with all its functioning parts. The computer would be unable to perform its task if the motherboard or the processor was missing, but this does not mean that they are the subjects of word processing. So it is a mistake to attribute the action of word processing to the processor or to the motherboard. Furthermore, it is not the hands of the writer that write the essay, but the person. The hands only press the keyboard. Again, the person would be unable to write the essay without his hands, but this does not mean that we should attribute "writing" to hands themselves. So the proper subject for the act of writing is not the hand of the person, it is the person that is writing.

Now, Bennett and Hacker argue that, by the same token, it is not the brain that is the proper subject of "perceiving," "experiencing," or "thinking," it is the person.

Despite the fact that there might not be a unified "self" or a "person" in some deep sense (Damasio 2012), we can attribute complex actions and thoughts only to beings that have self-regulated movement and are a part of some kind of linguistic community. In other words, it makes no sense to say that a being is thinking about its mother, if the being in question is incapable of intellectual life and expressing that life in some way or another (bodily action, language and so on). The point that Bennett and Hacker make here is that our everyday mental language does not really apply to things like brains, it only applies to beings with acting bodies and the capacity of complex linguistic expression. Thus, instead of simply attributing our actions to the brain, we need an account of how the brain is related to the way in which *we* "perceive," "experience," and "think."

Possible Contributions from Neurotheology

This section highlights several ways in which NT might contribute to the CSR. The main theme is the aforementioned tendency of cognitive theories of religion to focus on beliefs and concepts. In its modest forms, NT could provide evidence for and remind the cognitive scientist that there are many conscious, volitional, emotional, and experiential aspects in religious traditions.

The functionalist/computational paradigm is rather deeply entrenched in both the CSR (Boyer 1994, 2002) and in evolutionary psychology (Pinker 1997). In addition to understanding metal operations in terms of computation, the paradigm entails that the actual physical basis of thought is not really important. Since mental states are defined in terms of functional roles, the physical basis is "multiply realizable." That is to say, the same mental operation can be performed by different physical stuff: computers, human minds, or even large enough collections and organizations of cans of beer. The type of matter (nerve cells, silicon, etc.) does not make a difference with respect to thinking, only the way in which the matter is organized to perform is significant. Because of "multiple realization," the levels of information processing and its physical workings are independent from each other. It follows that the advocate of the functionalist/computational paradigm is unlikely to be interested in the way in which the brain actually realizes the different information-processing functions. As we have seen, this approach also directs the focus to belief and representation and away from other mental phenomena, like emotion, consciousness, volition, and imagination that are more difficult to conceptualize in computational terms. Although CSR admits that our cognitive processes are mostly "hot" instead of "cold," that is, emotional and volitional cognition often overrides abstract or more conceptual cognition, there is a tendency to focus on religious thinking in abstract, conceptual terms only.

By contrast, several neuroscientific studies point to many different kinds of emotional, physical, and volitional effects of religious and spiritual practices and experiences (e.g., Newberg and Waldman 2009). These results suggest that "conceptual" cognition is not separate (or wholly separate) from the emotional aspects of cognition. Indeed, some neuroscientists have argued that rational thinking is

impossible without emotional input (Damasio 1996). NT studies can function as reminders that there might be interesting religious phenomena that are difficult to study without taking into account the broader affective as well as cognitive experiences of religious subjects. This broader understanding might be particularly important in studying intense religious experiences.

NT could also contribute by producing evidence for or against certain assumptions that cognitive and biological theories make about how the human mind works. Cognitive scientists often postulate various information-processing modules and systems, such as the hypersensitive agency detection device (HADD), different mechanisms of social cognition, or the Theory of Mind mechanism. The assumption is that neural correlates for such mechanisms could eventually be found or at least their workings explicated in neuroscientific terms. Even if a cognitive scientist were strongly committed to the functionalist/computational paradigm, there would still be some kind of neuroscientific story to be told about the realization of specific information-processing modules. Conversely, let us say that no neuroscientifically valid story of the workings of some cognitive mechanism can be found. Even for the most hardened computationalist, this outcome would constitute at least *prima facie* evidence against the existence of such a mechanism as an independent entity.

Conclusion and Future Directions

In conclusion, let me highlight one critical issue that I have not explicitly discussed above. Behind neuroscience and cognitive science, the issue of consciousness and the nature of the "self" loom large (see, e.g., the brief analysis in Taves 2011). What is the relationship of cognitive and neuroscientific explanations to our conscious reasoning and to what extent these approaches account for the phenomenal qualities of our conscious experiences? Both NT and CSR (wisely) do not take strong views on this question. However, it might be that the issue of consciousness is not so easily bracketed. On the functionalist/computational theory of mind, phenomenal conscious states are either reducible to certain kinds of representations or they are epiphenomenal, that is, side effects of something else and have no effects by themselves. Further, many neuroscientists seem to think that since we cannot find consciousness or selves in the brain, there are no such things and everything humans do and think is explained in terms of the physical operations of the brain. Now, the computational theory and the cruder forms of neuroscientific reductionism are not without their critics. The computational view has been subjected to sustained criticism from both neuroscience and philosophy (e.g., Searle 1989; Fodor 2000). Similarly, the excessive use of neuroscience has been strongly criticized by, e.g., Raymond Tallis and others (Tallis 2011). The main critical point, it seems, is that both neuroscience and computational cognitive science are unable to make sense or take into account the phenomenal aspects of consciousness and the "aboutness," intentionality, of mental states and are, thus, ill equipped to deal with explicitly conscious aspects of human behavior and thought.

To fend off possible misunderstandings, let me also emphasize what I did *not* argue in this chapter. The argument was *not* that all forms of neurotheology should be rejected. The aforementioned arguments against approaches that focus on religious experiences need not entail a total rejection of NT. What they do entail (if correct) is that a neuroscientific study of religious experiences might not be the best starting point of a general theory of religious thought and behavior. Furthermore, the aforementioned arguments apply to some forms of NT only to some extent or none at all. NT in its programmatic form is clearly the main target of these criticisms. If one is a representative of NT in its narrow sense, the criticisms might not apply at all. If one is sufficiently modest and interested in studying the neural correlates of, say, experiences associated with trance-like states, one need not make sweeping claims about there being an experiential essence to such experiences cross-culturally or that one could develop a theory of religion on the basis of such a research. In addition, NT in its narrow sense need not entail that the experiences that neuroscientists study are not conceptually structured or conditioned. Again, the argument is not that NT is useless, but that it needs to be more modest in its claims.

As for the future of the scientific study of religion, it seems to me that we need neuroscience and cognitive science as well as explicitly evolutionary approaches. Religion is a multi-faceted phenomenon that has its roots in the way we human beings are and how we have evolved. This includes our brains as well as our minds. There is a desperate search for both conceptual tools and empirical data that would help us evaluate current theories and relate them to one another. Here the future scientific and philosophical developments around two major interfaces, the brain/cognition (neuroscience/psychology) and cognition/conscious thinking, will most likely provide useful insights into religion as well.

Model-Based Religious Reasoning: Mapping the Unseen to the Seen

Contents

Abstract

Contrary to what might be commonly believed, there is a family resemblance between model-based reasoning in the sciences and popular religious reasoning. Model-based reasoning factors into popular religious reasoning in large part due to the role that model-based reasoning plays in social cognition generally, and the role that social cognition in turn plays in thinking about extra-natural agents. Specifically, popular religious reasoning can be considered as an instance of the human tendency to isolate the structural features of peculiar events and to match these features to some overall view of the world. The procedure is not unlike the use of a particular map while hiking, with certain features that stand out in the terrain matched to symbols on the map. Just as one can interpret one's environment in terms of a preexisting map (a "top-down" approach), however, it is also possible to abstract the structural features of one's environment to create a new map (a "bottom-up" approach). This chapter suggests that one can think of natural theology as a form of bottom-up model-based reasoning, one that mirrors the top-down model-based reasoning common in popular religious reasoning.

Introduction

One does not have to be an atheist for much popular religious reasoning to seem peculiar or even intrinsically irrational. From a perspective formed by a scientific outlook, popular religious explanations, such as that cancer is caused by witchcraft, that socioeconomic privileges reflect karma, or that a tsunami is an act of divine judgment, seem well beyond the warrant of the available evidence and harmful to true understanding. Moreover, popular religious explanations for cases of fortune and misfortune, origin and purpose, can seem far removed from the refined use of reason one finds in natural theology as well as the rigors of scientific explanation. Contrary to initial appearances, however, this chapter aims to show that the pattern of thinking involved in popular religious reasoning bears at least a family resemblance to model-based reasoning in the sciences as well as to natural theology.

Model-Based Reasoning

To explicate model-based reasoning in general, this section follows an approach in the spirit of Ronald Giere's model-based philosophy of science, especially as developed in Giere (2006). Rather than Giere's claim that maps and models are merely analogous, however, and that maps are physical objects whereas models are abstract entities, this section proposes that maps can be instantiated inside or outside the mind, and are one species of a more general class that one can usefully identify as that of "models."

Consider the example of using a map while on a hike. What exactly makes the piece of paper in one's hand successful as a "map," able to help one to navigate reliably and safely? One possible answer would be that the piece of paper is a map, because it represents the terrain. Unlike the way a king's seal represents the approval of a king, however, the map represents the terrain due to the fact that it resembles the terrain. Nevertheless, resemblance alone does not suffice to account fully for what makes something a map, since all pieces of paper resemble the terrain in at least some sense, such as both being physical entities. Moreover, there will be many things the map resembles more than the terrain, such as other copies of the same map.

To a first approximation, what makes the piece of paper a map is that it resembles the terrain due to the manipulation of the spatial relationships of items on the paper so as to track the spatial relationships of certain features of the terrain. One can have trivial and even accidental instances of such a resemblance. For instance, one's living room furniture can happen to be arranged in a way that corresponds to the layout of Trafalgar Square. In the case of maps, however, the resemblance between the map and what it is a map of is *intentionally* proportional, with the selected features and their proportionality being tied to a set of intended uses to which the map can be put. The degree of resemblance does not have to be too high for a piece of paper with symbols on it to function as a map, and indeed too much detail can be unhelpful. Rather, the resemblance has to be sufficient for the map to be used for its intended purposes, such as navigation on a hike.

In order to make use of a map to reason about one's future courses of action, however, one also needs to know how to match what one can observe in one's surroundings to part of the map, thereby unlocking further information from the map about various other matters in one's surroundings that one cannot observe directly. For example, a conventional symbol on a map may assist in discovering whether a building in the distance is a ranger station or a private residence. The map may also provide insight by placing what is observable into a larger context that cannot be observed directly, such as when one wants to discover exactly how much farther one has to hike before making it back to civilization. Moreover, it should be noted that, beside particular facts about local geography, consulting the map may also produce a Gestalt effect, allowing one to organize mentally what is observed on the terrain in the light of the structure of the map.

The features of maps and map-based reasoning identified here apply much more broadly. Translating the relational structure of something into the relational structure of a different thing need not take the form of translating spatial relationships in the target into the spatial relationships of a representational proxy. A bar graph depicting the proportion of redheads in the population does not resemble the way redheads are spatially located in the world vis-à-vis others, not least because there is no box-like pile of redheads anywhere in the world. Nevertheless, the spatial structure of the representation, rather than convention or causal history alone, communicates the intended information by resembling, albeit by means of an abstraction, some selected features of the world. The broader category that includes maps, without being limited to them, may be called "models." Models in general take relational structures in one domain and use them as a way to gain cognitive understanding of equivalent relational structures in another domain.

Such a definition is, of course, extremely broad and mention should be made in passing of the many important differences between various kinds of model-based reasoning. First, for example, it may be the case that reasoning with models about complex relationships in a visual modality is slower than using more abstractly represented models, perhaps due to cognitive noise created by extraneous visual detail (cf. Knauff et al. 2003; Knauff and May 2006). Second, using an external representation of a model may change the nature of the internal operations employed by model-based reasoning. What may be the same model may engage reasoning processes that are quite different depending on what cognitive tools are available. See, for instance, the classic case study of reasoning in navigation in Hutchins (1995). Nevertheless, such differences do not exclude an underlying family resemblance between the various kinds of models and model-based reasoning that we use (cf. the general theory presented in Goodwin and Johnson-Laird 2005 which is supposed to apply cross-modally).

Within this broad definition, it is quickly evident that models play an important role in scientific reasoning and explanation (cf. Frigg and Hartmann 2012; Giere 1988, 2006; Thagard 2012). Consider the following generic example. Suppose that data points are plotted on a two-dimensional coordinate system. The x and y axes of the coordinate system represent, in graphical form, two experimentally observable and measurable characteristics of the target(s) of one's research, characteristics that

may not themselves be spatial, such as a heat capacity and a temperature. One may think of the plot of points as an instance of a model such that the relation of the points plotted in the coordinate system stands for a relation of another, non-spatial type in the target domain. Typically, outliers in the collected data are then discounted and a curve is fitted through the critical concentrations of data on the coordinate system. The result is a model of the original data that simplifies what is taken to be relevant so as to make it more usable and, in particular, more usable for theorizing. Although there are deep philosophical questions about the nature of this process, such work is done in the hopeful expectation that the idealized model of the data approximates some underlying causal structure of the world.

Modeling, however, can also be used in science in a slightly different way, namely, in comparing experimental data with some theory that is already known, either for the purpose of interpreting the data or testing the theory. In fact, there is a more restrictive use of the term “model,” tied to formal methods in logic and computation, that would seem to apply most naturally to models of this sort (cf. Hodges 1997; Thagard 2012). In contrast to the previous example, one already has a theory about some deep underlying causal structure of the world prior to conducting the experiment and one wants to relate the data obtained to theoretical entities that are not themselves directly observable. What is needed is the ability to map the data about observable properties, plotted in a curve on a two-dimensional coordinate system, onto relationships between purported theoretical entities. To achieve this goal, one will often need to develop a representation of the theory’s structural properties or translation schemes for those properties that are amenable to comparing the structure of one’s theory and the structure of one’s data.

The latter kind of modeling is important for a number of reasons. First, even when theories take the form of universal rules, they may have adjustable parameters or various kinds of idealizations that require the mediation of a model that maps them onto specific contexts so that their predictions can be compared to experimental data. Theories of physics, for instance, are often described in terms of idealizations, such as frictionless planes or closed two-body systems, that invariably have to be related to the conditions of an actual experiment, normally by means of some kind of model, in order to assess the degree of resemblance of the theory to relevant features of the world. An example is the way that particle physicists have to model their own experimental apparatus in great detail in order to relate the effects of proposed universal laws to the details of an actual experiment, with varying kinds of signals, “dead space” (unresponsive parts of the detector), and so on. Second, the theory can be richer in information than one’s available data, so that a partial, simplified representation of the relevant theoretical domain is needed in order to make a meaningful or practical comparison, as in the case of the hiker who needs a map to give directions for walking and not, for example, details of the underlying geology of the landscape. Third, theories themselves may often be in the form of models that capture some but not all of the characteristics of an actual physical system, such as a billiard ball model of a gas or a computer model of the brain.

Finally, it should be noted that scientific modeling can also be effective in theoretical and practical terms even when the underlying physical causes remain opaque. Consider, for example, the transition in the nineteenth century from the miasma theory to the waterborne theory of cholera (cf. Johnson 2006). In the 1850s, no one could explain the agency that produced cholera, why the disease manifested itself with the symptoms that it did, or predict where it would occur. Nonetheless, it was possible to compare one theory, that cholera was caused in some unknown way by exposure to the atmosphere in certain poor parts of a city, with the alternative championed by Dr. James Snow, that the disease was somehow caused by tainted water. What Snow did was to construct a map of the deaths due to cholera in relation to particular sources of water. The concentrations of the disease around particular water supplies were sufficient to allow Snow to demonstrate the efficacy of his theory over its competitor, even though both theories lacked any account of the underlying physical cause of the correlations between the water and the disease, namely, the spreading of the bacterium *Vibrio cholerae*.

Models, then, clearly enter into scientific reasoning in a wide variety of ways: as idealizations of experimental data that may also indicate underlying causal structures of the world; as means to compare proposed theoretical entities with experimental data; and as ways of uncovering correlations between empirical phenomena even when the underlying causes remain opaque. In all these and other ways in which models and model-based reasoning enter scientific practice, they enable new insights by mapping structural features in one domain onto another domain, even in the absence of a wholly satisfactory account of the underlying causes of the observed phenomena.

Social Reasoning and Popular Religion

Besides specialized applications in the sciences, model-based reasoning is arguably ubiquitous in everyday life and especially in the social domain. Overt references to models and model-based reasoning in the mind-reading discussion are relatively rare at present, exceptions being Peter Godfrey-Smith and Heidi Maibom in their accounts of social cognition (Godfrey-Smith 2005; Maibom 2009). Nevertheless, as will be shown, describing various kinds of social cognition in terms of model-based reasoning is quite intuitive. Moreover, much research in the cognitive science of religion has converged on the thesis that a great deal of what goes on in religious thinking is subserved by everyday social cognition redeployed to extra-natural agents (Cf. Atran 2002; Barrett 2004; Bering 2011; Boyer 2001; Guthrie 1993; McCauley and Lawson 2002). Hence if model-based reasoning is important for social cognition, it is also important for neurotheology. More specifically, model-based reasoning is plausibly central to the crucial transition between the “mere” detection of some purported agency, whether human or divine, and an understanding of the inferred agent’s perspective and possible future behavior.

How then does model-based reasoning enable this transition to more complex kinds of theological reasoning than agency detection? As a more immediately familiar example of how such model-based reasoning works in everyday life, suppose that a child called Suzie steals the favorite action figure of her sibling, Tommy. The next morning Suzie does not find the stolen action figure where she had hidden it, but instead sees her favorite comic book ripped neatly in two. Suzie quickly comes to the conclusion that the ripping of the comic book was an intentional, retaliatory action on the part of Tommy, even though she did not see Tommy rip her book and was not told by anyone that he did so.

How does Suzie come to this conclusion? It would be psychologically unrealistic to attribute to Suzie the possession of a set of universal rules of human psychology that are so detailed and encompassing as to contain information about comic books and their demise. A much more plausible gloss is as follows. Suzie has certain expectations about how the world works. Against the backdrop of these expectations, the fate of the comic book stands out as a singular and unnatural state of affairs best understood in terms of intentional action rather than the standard, non-agential way in which events usually transpire. Having represented the ripping of the comic book as intentional, Suzie matches this action against her relationships with possible perpetrators. The action does not fit her normal expectations for how Tommy behaves, but it is easier for her to attribute the ripping of the comic book to an intentional action of Tommy than for her to see it as an accident or the action of someone else. Moreover, given the special circumstance, namely, that she has just stolen Tommy's favorite action figure, and that the action figure is now missing from her possession, a possible indication that Tommy has discovered the theft and recovered his property, she concludes that he has a possible motive for retaliation. She therefore concludes that Tommy ripped her comic book.

Suzie can be usefully thought of as engaging in model-based reasoning at each of the levels covered in the previous section. She identifies an anomaly in her environment, perhaps against the backdrop of a general model of the world and how it should unfold over time when not interfered with by agents. She isolates the relevant features of the anomaly and uses those features to fit the ripping of the comic book into the "effect" slot of her intentional action schema. She then looks to fill out that schema either by consulting a standing model of the psychologies of her family members or by enacting a new model of them through imagining herself in their respective positions. She consults the recent history of her relationships, which allows her to bridge the gap between her model of what has happened to her comic book and her general psychological model of her brother. This allows her to form a new psychological model updated with the special circumstances surrounding the stolen figurine that fits nicely with the tearing of the comic book and gives Suzie a useful explanation of what has happened.

No doubt there are differences between what Suzie does and what scientists do when they engage in model-based reasoning. For one thing, Suzie is probably more likely to apply her models as heuristics instead of through explicitly considered and endorsed discursive reasoning. Suzie recognizes a fit between what are, in fact, models, but she is not likely to be fully aware at a meta-level of what she is doing

when she reasons this way. The claim is not, of course, that heuristics are not also used in science. The work of Herbert Simon and Gerd Gigerenzer, for example, gives one reason to suspect that heuristics will generally be involved in mature, specialized cognition rather than being a mere "vice" of untrained and unreflective reasoning (cf. Simon 1977; Gigerenzer 2008). Rather, Suzie's social cognition is more likely to be what Bob McCauley calls "maturationally natural," like learning to walk or speak, whereas scientific model-based reasoning requires "practiced naturalness," like learning to ride a bike or play the piano (McCauley 2011).

Despite such differences, however, a family resemblance remains between scientific model-based reasoning and what Suzie does. Both processes seek to identify relational structures and map them against other relational structures in an effort to explain some aspect of the world. Moreover, these processes rely on something that is apparently like modeling both at the level of conceptualizing the *explanandum* and at the level of bridging the gap between the *explanandum* and candidate *explanantia*. Furthermore, in both cases, the key to successful model-based reasoning is to develop a representation of a target phenomenon that helps connect that target to a more general picture of the world.

The pattern of steps that takes place in social scenarios such as these also seems similar to much popular religious reasoning. Whatever a religious person thinks of religious experience, she should be amenable to the idea that religious explanations that are not rooted in qualitatively unique experiences are processed through a redeployment of whatever mental machinery is normally involved in social explanations. Nevertheless, setting aside cases that are experienced by the subject in some way that is especially conducive to the attribution of extra-natural agency, for what reason would such agency normally be invoked as an explanation?

One possibility is that the reasoning is similar to how Suzie comes to the conclusion that Tommy has ripped up her comic book. Some event strikes a person as peculiar, a deviation from the normal course of things that suggests that it is the effect of some intentional action: for example, the event might promote or contravene one's own interests more than one would expect to be true of a genuinely random event; or perhaps the peculiar features in question resemble the intentional design of human artifacts. If the cast of possible natural agents does not account for the putative intentional action, then one is faced with a disjunction. Either, contrary to appearances, the event is a random fluctuation in the normal course of things, or an extra-natural agent is involved. If one's metaphysics includes extra-natural agents who can intervene in the world, and their motives and interests can be matched to the event, explaining the event in terms of such agency is as understandable as Suzie inferring an intentional explanation for what happened to her comic book rather than her supposing that the book spontaneously divided into two apparently ripped pieces.

The foregoing account should not be taken to imply that the peculiar events that elicit this kind of religious reasoning must be taken to be rare, or that the reasoning involved is always as uncontroversial as it is in the case of Suzie's comic book. Depending on one's cultural context, temperament, and perhaps character, one might ascribe events to extra-natural agency quite promiscuously.

Rather, the key idea is that the events in question are taken to stand out as having a structure that deviates from the normal way of things in the absence of intentional action. Consider, for example, the following anecdote recorded by the anthropologist E. E. Evans-Pritchard, concerning a boy of the Zande people, who see witchcraft as permeating life.

> A boy knocked his foot against a small stump of wood in the centre of a bush path, a frequent happening in Africa, and suffered pain and inconvenience in consequence. Owing to its position on his toe it was impossible to keep the cut free from dirt and it began to fester. He declared that witchcraft had made him knock his foot against the stump. . .I told the boy that he had knocked his foot against the stump of wood because he had been careless, and that witchcraft had not placed it in the path, for it had grown there naturally. He agreed that witchcraft had nothing to do with the stump of wood being in his path but added that he had kept his eyes open for stumps, as indeed every Zande does most carefully, and that if he had not been bewitched he would have seen the stump. As a conclusive argument for his view he remarked that all cuts do not take days to heal but, on the contrary, close quickly, for this is the nature of cuts. Why, then, has his sore festered and remained open if there were no witchcraft behind it? (Evans-Pritchard 1976, p. 304)

In this passage, the boy reasons to the conclusion that witchcraft had made him knock his foot against a stump and prevented the wound from healing, and Pritchard records many structurally similar cases from his study of the Zande people. In each case, what comes to the fore is an event that deviates from the way things are supposed to go in some peculiar fashion that is to one's detriment. In the Zande culture, there is a general background belief that misfortune is often caused by witchcraft, and thus, it is easy to map the unseen forces of witchcraft onto the observable features of the misfortune.

Commenting on the case of the boy from the cited story, Evans-Pritchard says,

> The boy who knocked his foot against a stump of wood did not account for the stump by reference to witchcraft, nor did he suggest that whenever anybody kicks his foot against a stump it is necessarily due to witchcraft, nor yet again did he account for the cut by saying that it was caused by witchcraft, for he knew quite well that it was caused by the stump of wood. What he attributed to witchcraft was that on this particular occasion, when exercising his usual care, he struck his foot against a stump of wood, whereas on a hundred other occasions he did not do so, and that on this particular occasion the cut, which he expected to result from the knock, festered whereas he had dozens of cuts which had not festered. Surely these peculiar conditions demand an explanation (ibid, p. 305).

What is the boy doing? He isolates the peculiar features of the event, which include stubbing his toe while being attentive and the resultant cut being especially slow to heal. He then privileges these features to the exclusion of all the other details that surround the event. He, thereby, creates a model of what is salient at the level of the data to be explained. He then identifies a fit between his model of what has happened to him and the rather general, cultural model according to which bad things that happen, despite responsible behavior, are due to witchcraft. In the absence of a practical reason to pursue a deeper explanation, the boy is satisfied with the general match between the circumstances of his injury and the category of witchcraft.

The exact form that model-based religious reasoning takes will of course depend on all manner of circumstances, such as the kinds of extra-natural agents a given culture takes to exist, and under what conditions one can expect the interests of agents of those kinds to intersect with one's own interests. If someone believes in the prevalence of witchcraft, she might expect that any extraordinary event that would be in the interests of a normal human agent to bring about, but which seems impossible to account for in terms of a normal human agent exercising normal human powers, is a candidate for extra-natural explanation. By way of contrast, a consistent deist may make use of the model of a designer or creator in explaining some of the world's features, but her operative model of the world cannot permit the introduction of special divine action as a possible causal explanation of events in her environment on pain of inconsistency.

The form that model-based reasoning takes will also depend on what models are available as heuristics for applying the more complex, official doctrines of a religion, especially one for which the content of divine revelation cannot be captured adequately by any one model. For example, a Christian typically resorts to a wide range of metaphors and analogies for God, such as that of father, judge, creator, shepherd, wronged lover, warrior, and many other personal roles and even inanimate things, such as a rock or a consuming fire. Some of these models may be more appropriate than others in particular kinds of model-based reasoning, in particular circumstances. For example, the reasons that a judge would allow one to suffer, for example, could well differ from the reasons that a loving father would have for permitting suffering. Both these metaphors, as used in particular model-based reasoning processes, however, capture diverse facets of the officially sanctioned Christian understanding of the divine.

Nevertheless, although model-based reasoning in religious matters is extremely diverse, even within a single faith tradition, what does seem plausible is that some kind of modeling is required for any kind of explanation involving unseen intentional agency and, moreover, that the cognitive processes involved share at least some family resemblance with model-based reasoning in other areas of life, including the sciences. A religio-cultural superstructure may also be present and help to regulate the models of extra-natural agency people employ, as well as the degree of fit between such models and unusual events that is considered sufficient to justify acting on a perceived fit. There is reason to think that the basic models of folk psychology, however, may be so robust as to be very hard for a religious authority to constrain. For instance, religious people routinely reason with models of their gods that are anthropomorphic in respects not licensed by official doctrine (see, for example, Sloan (2004); Barrett and Keil (1996)).

Finally, the family resemblance of model-based reasoning in both religious and scientific reasoning also hints at some of the ways in which one might evaluate a specific instance of popular religious reasoning on its own terms. Some features of model-based reasoning that could be used to evaluate such reasoning as warranted or not include: whether one's degree of belief in the conclusion is proportional to the degree of fit between the model and the data; whether the former is sensitive to the latter or a match can be accounted for by accident; whether the pattern of one's

data is genuinely distinctive relative to competing models; whether one has been appropriately sensitive to other patterns that might be in the data; whether the model one applies to the data is internally consistent; whether the model is independently well-founded; and whether one has submitted one's own reasoning to whatever external checks may be available. For example, if we were to evaluate the reasoning of the Zande boy who cut his foot on the stump, we might have cause to criticize the boy's reasoning along one or more of these lines: we might point out that there does not seem to be any reason to expect that a witch would be interested in cutting the boy's foot, and thus, the fit between the anomalous experience and the model he is using may not be as tight as he thinks; alternatively, we might challenge how distinctive the boy's experience really is, or the general warrant for the witchcraft model of misfortune. What one should not do, however, is simply consign what the boy does to the category of "un-reason." Even if the boy's beliefs operate largely at a subliminal level, what the boy does is engage in a kind of reasoning, the pattern of which is not as unfamiliar as it might appear.

An Application to Natural Theology

As a coda to the previous sections, notice that model-based reasoning can work in either of two directions. The primary concern of a hiker is to find a map that she can trust and then to match her surroundings to the map so as to navigate the terrain. A mapmaker, on the other hand, works from the other direction, abstracting from his observations of the terrain to a composite representation of the whole.

As noted previously, the bidirectionality of model-based reasoning is present in the scientific and social domains as well as navigating physical maps. Model-based scientific reasoning need not be tied only to interpreting one's findings but can be used to generate and test new theories. James Snow's map of a cholera epidemic mentioned previously could have inspired a waterborne theory of cholera if Snow had not already formulated it. In the social domain, we do not simply interpret the behavior of persons in terms of our previous expectations. We construct new expectations on the basis of present behavior, and revise our models in light of the course of our relationship with others.

Natural theology, ultimately, tries to establish some theological truths with natural reason. In an early article in his *Summa theologiae* (*ST*), Aquinas takes up the question of whether it can be demonstrated that God exists. He replies in the affirmative:

> When an effect is better known to us than its cause from the effect we proceed to the knowledge of the cause. And from every effect the existence of its proper cause can be demonstrated, so long as its effects are better known to us; because since every effect depends upon its cause, if the effect exists, the cause must pre-exist. Hence the existence of God, in so far as it is not self-evident to us, can be demonstrated from those of his effects which are known to us (*ST* I q.2 a.2).

Aquinas goes on in the five ways to isolate different structural features of the natural world and to argue that they imply the existence of a certain kind of minimally described extra-natural being. Although Aquinas's famous proofs are deductive in form, in light of the discussion of model-based reasoning above, it is tempting to gloss what is happening here as "bottom-up" model-based reasoning. Just as Snow's map of the cholera outbreak identified a pattern in an effect that implied a corresponding structure in the cause of that effect ("something in the water causes cholera"), so Aquinas aims to demonstrate the existence of God under the minimal descriptions necessary for God to be the cause of a natural world with the structural properties Aquinas identifies: movement requires a first mover; an ordered series of causes needs an uncaused cause; teleology and purpose imply some undergirding intelligence that can imbue something with purpose and so on. For a rigorous reconstruction of Aquinas' five ways, see Pawl (2012).

Comparing this approach with the cases considered previously, my suggestion is that the way to see the contrast is that natural theology fits most appropriately with bottom-up model-based reasoning, whereas popular religious explanations are typically instances of top-down model-based reasoning. To express the contrast another way, natural theology is akin to map-making, whereas popular religion is akin to hiking with a preexisting map. Either can be done skillfully, but the former pairing is more specialized than the latter pairing. The average person has neither the time, the training, nor the motivation to attempt to generate or refine a model of the extra-natural. For ordinary interests, it is sufficient to take one's cultural inheritance and seek to apply it to one's circumstances to help navigate a path through life. This contrast, however, does not mean there is not some family resemblance between the two forms of religious reasoning or, indeed, between both of these forms and model-based reasoning in the sciences.

Conclusion and Future Directions

What model-based reasoning in the sciences, natural theology, and popular religious explanation all involve is navigation between the relational structures of the observable, natural world and whatever deep explanatory beings or structures are purported to lie beyond the limits of normal observation. Keeping this family resemblance in mind can help render intelligible, according to their own terms, processes of thought that many today might otherwise find especially peculiar about popular religious reasoning.

Some further questions that bear investigation are as follows.

Helen De Cruz has been doing groundbreaking work trying to give an explanation in terms of cognitive science of why certain traditional arguments for God's existence such as the teleological and cosmological arguments have perennial appeal (Cf. De Cruz 2010, 2011). Along these lines, there is a great deal of work to be done in analyzing the models and forms of reasoning that lie behind specific arguments and discussions within either popular religion or theology.

For instance, what are the models that might inform: a cyclical versus a linear view of time, rival perspectives on providence and free will, or various forms of theodicy?

Another question that merits investigation concerns the way in which one ends up deciding between rival models. The rival models could be found either between different religions, as when someone has a cultural background that allows them to slip between a cyclical and a linear view of time, or within a religion, as when one must decide to make sense of one's experience through a model of God as a loving father, a righteous judge, or a warrior battling evils.

Abstract

Interaction with the world requires the right hemisphere's broad attention, which is inclusive and opens up into possibility, coupled with the left hemisphere's narrow attention, which collapses the world we experience into specificity. If the left hemisphere collapses the world too quickly into what is specific, however, it precludes the possibility of knowledge that transcends what is already familiar, notably purported knowledge of the divine. By contrast, the right hemisphere is more sensitive to image, metaphor, and narratives by which theological knowledge may be capable of expression that would be ambiguous or apparently contradictory if expressed simply as a set of propositions. The reciprocal organization of the cerebral hemispheres therefore suggests that any proposed theology that is articulated simply in terms of a set of specific propositions about the divine risks betraying, distorting, and misrepresenting its subject matter. Furthermore, this organization of brain structure and function suggests that images, metaphors, and narratives are not poor substitutes or intermediate steps in theological knowledge, but indispensable to it.

Introduction

How does one know, or at any rate become aware of, what it is that one does not know? This is, of course, a fundamental epistemological problem, since the openness required to embrace propositions that cannot be demonstrated to follow necessarily from commonly held truths leaves one open to the possibility of self-deceit. And yet not to be aware of what it is one does not know is also, inevitably, to deceive oneself.

Language and Hemisphere Differences

Not all knowledge is, however, propositional in nature. Ultimately, in fact, all knowledge derives from experience, for which there are no propositions, and many languages express at least some aspect of this difference by distinct words for the ways in which one can be said "to know." *Sapere* bows to *cognoscere*, *savoir* to *connaître*, *wissen* to *kennen*. When we say we know something, what we mean is that we see that it is like something else that we reckon we already know better. And those "somethings else," followed far enough, return us in every case to embodied experience. Additionally, both the first propositions, or axioms, from which we reason, and even the value of reason itself as a tool for the discovery of truth, have to be intuited. We cannot reason our way to either.

Since language embodies thought, it follows the same path. Words are like money. In any (apparently) enclosed financial system, any number of "virtual" transactions can be carried out, but in the end, all such transactions depend on money taking its value from somebody's cows or chickens somewhere, and being translated back into real goods or services – food, clothes, car repairs – in the realm of daily life somewhere else. So it is with words. Webs of thought can be spun with them, but ultimately language represents something valuable elsewhere: Its value lies only in what it represents in the world of embodied experience.

For this reason, language is essentially, not accidentally, metaphorical in nature. Even the most abstract of terms, such as the word "virtual" itself, take us back ultimately to the earthy reality of a man's strength (*vir-tus* in Latin). Metaphor embodies thought and places it, where it belongs, in a living context. In this, it bridges the gap between language and the world, a gap entailed on us by the very nature of language. The language of science and philosophy is not only no exception to this, but a particularly obvious example of it.

Thus both the process of reason and its axioms, and the business of linguistic discourse and its terms, ultimately depend on and cannot transcend intuitive knowledge and embodied experience. Following intuition may lead us astray, right enough, but so may not attending to it: There is a wealth of evidence that those who rely on ratiocination alone make poorer judgments than those who combine reason with intuition, and often they can barely function in the world at all.

What does all this have to do with the brain? In humans, as in other mammals, as well as in birds, reptiles, and even fish, the brain is divided. This is odd, because the brain exists to make connections and is only as powerful as its connections. Odder still, the band of fibers that connects the hemispheres, the corpus callosum, has grown proportionally smaller (in relation to hemispheric volume) with evolution (Jäncke and Steinmetz 2003; Hopkins and Marino 2000; Aboitiz et al. 1992), and much of its activity in any case involves functional inhibition of the contralateral hemisphere. The corpus callosum contains an estimated 300–800 million fibers connecting topologically similar areas in either hemisphere. Yet only 2 % of cortical neurons are connected by this tract (Jäncke and Steinmetz 2003; Banich 2003). What is more, the main purpose of a large number of these connections is actually to inhibit – in other words to stop the other hemisphere interfering. Neurons can have an excitatory or inhibitory action, excitatory neurons causing further neuronal activity downstream, while inhibitory neurons suppress it. Although the majority of cells projecting to the corpus callosum use the facilitatory neurotransmitter glutamate, and are excitatory, there are significant populations of nerve cells (those that use the neurotransmitter gamma-amino butyric acid, GABA) whose function is inhibitory. Even the excitatory fibers often terminate on intermediary neurons, or interneurons, whose function is inhibitory (Conti and Manzoni 1994; Saron et al. 2002). Inhibition is, of course, not a straightforward concept. Inhibition at the neurophysiological level does not necessarily equate with inhibition at the functional level, any more than letting your foot off the brake pedal causes the car to halt: Neural inhibition may set in train a sequence of activity, so that the net result is functionally permissive. But the evidence is that the primary effect of callosal transmission is to produce *functional* inhibition (Meyer et al. 1995; Röricht et al. 1997; Höppner et al. 1999). So much is this the case that a number of neuroscientists have proposed that the whole purpose of the corpus callosum is to allow one hemisphere to inhibit the other (Cook 1984; Hoptman and Davidson 1994; Chiarello and Maxfield 1996). Stimulation of neurons in one hemisphere commonly results in an initial brief excitatory response, followed by a prolonged inhibitory arousal in the contralateral hemisphere. Such inhibition can be widespread, and can be seen on imaging (Saron et al. 2003; Allison et al. 2000; Tootell et al. 1998).

There would appear to be an evolutionary adaptation here that connects, but also importantly separates, two spheres of cerebral activity. Why?

Birds and other animals have to solve a conundrum on which their survival depends, namely, how to eat and to stay alive at the same time. Each must pay attention to something that is already prioritized – a seed, one's prey – at the same time as being open to whatever it is that might come along during the process – be it predator or conspecific. For the first of these, one needs narrow-beam, sharply focused attention to something that is already prioritized; for the latter, one needs precisely the opposite, namely, a broad, open, vigilant, sustained attention without commitment as to what may be found. Paying two kinds of attention in one consciousness at the same time is an almost intractable problem. The solution appears to have been the bihemispheric brain. The left hemisphere in birds and other animals provides narrow attention in order to get food, to pick up a twig to

build a nest, and in general to *manipulate* the world; the right hemisphere provides a broad picture that makes it possible to watch out for predators and bond with mates, and more generally to *understand*, and to find oneself standing in relation to, the world at large. Unsurprisingly, therefore, chicks that are properly lateralized (whose hemispheres are appropriately differentiated) are more able to use these two types of attention effectively than are those in whom, experimentally, lateralization has not been permitted to develop (Rogers 2000). Many types of bird show more alarm behavior when viewing a predator with the left eye (right hemisphere) (Hoffman et al. 2006), are better at detecting predators with the left eye (Rogers and Kaplan 2006; Rogers 2000), and will choose to examine predators with their left eye (Rogers et al. 2004), to the extent that if they have detected a predator with their right eye, they will actually turn their head so as to examine it further with the left (Dharmaretnam and Rogers 2005). Hand-raised ravens will even follow the direction of gaze of a human experimenter looking upward, using their left eye (Bugnyar et al. 2004). For many animals, there are biases at the population level toward, again, watching out for predators with the left eye (Evans et al. 1993; Rogers 2000; Lippolis et al. 2002, 2005). In marmosets, individual animals with more strongly lateralized brains are better able, because of hemisphere specialization, to forage and remain aware of predators (Rogers 2005). There are shorter reaction times in cats that have a lateralized paw preference (Fabre-Thorpe et al. 1993). Lateralized chimps are more efficient at fishing for termites than unlateralized chimps (McGrew and Marchant 1999). Even individual human brains that are, for one reason or another, less lateralized than the norm appear to show global deficits (Crow et al. 1998). In a word, lateralization brings evolutionary advantages, particularly in carrying out dual-attention tasks (Rogers et al. 2004). As one researcher has put it succinctly: Asymmetry pays (Güntürkün et al. 2000).

In predatory birds and animals, it is the left hemisphere that latches on, through the right eye and the right foot, to the prey (Csermely 2004). It is certainly true of familiar prey: In toads, a novel or unusual choice of prey may activate the right hemisphere, until it becomes familiar as an object of prey, when it once again activates the left (Robins and Rogers 2006). In general, toads attend to their prey with the left hemisphere, but interact with their fellow toads using the right hemisphere (Vallortigara et al. 1998).

The advantages accrue not only to the individual: Being a more lateralized species at the population level carries advantages in social cohesion (Bisazza et al. 2000; Rogers and Workman 1989; Halpern et al. 2005). That may be because the right hemisphere appears to be deeply involved in social functioning, not just in primates, where it is specialized in the expression of social feelings, but in lower animals and birds as well (Fernández-Carriba et al. 2002; Ventolini et al. 2005). For example, chicks preferentially use the left eye (right hemisphere) for differentiating familiar members of the species from one another, and from those who are not familiar, and in general for gathering social information (Rogers 2000; Vallortigara 1992). Chicks approach their parents or an object on which they have imprinted using their left eye (Dharmaretnam and Andrew 1994), as do Australian magpies (Hoffman et al. 2006). Though black-winged stilts peck more, and more

successfully, at prey using the right eye (left hemisphere), males are more likely to direct courtship displays to females that are seen with their left eye (right hemisphere) (Ventolini et al. 2005). The right hemisphere is the main locus of early social experience in rats (Denenberg et al. 1978). In most animal species, intense emotional responses are related to the right hemisphere and inhibited by the left (Andrew and Rogers 2002).

In humans, too, the hemispheres attend to the world differently. Since attention is involved in the genesis of our experiential world, so that the quality of attention we pay affects what it is that we find, this has important consequences for the type of world each hemisphere helps to mediate for us.

Attention is not just another "function" alongside other cognitive functions. Its ontological status is of something prior to functions and even to things. The kind of attention we bring to bear on the world changes the nature of the world we attend to, the very nature of the world in which those "functions" would be carried out, and in which those "things" would exist. Attention changes *what kind of* a thing comes into being for us: In that way, it changes the world. If you are my friend, the way in which I attend to you will be different from the way in which I would attend to you if you were my employer, my patient, the suspect in a crime I am investigating, my lover, my aunt, a body waiting to be dissected. In all these circumstances, except the last, you will also have a quite different experience not just of me, but of yourself: You would feel changed if I changed the type of my attention. And yet nothing *objectively* has changed.

So it is, not just with the human world, but with everything with which we come into contact. A mountain, that is a landmark to a navigator, a source of wealth to the prospector, a many-textured form to a painter, or to another the dwelling place of the gods, is changed by the attention given to it. There is no "real" mountain which can be distinguished from these, no one way of thinking which reveals the true mountain.

It is often wrongly thought, however, that science uncovers such a reality. Its apparently value-free descriptions are assumed to deliver *the* truth about the object, onto which our feelings and desires are later painted. Yet this highly objective stance, this "view from nowhere," to use Nagel's phrase, is itself value-laden (Nagel 1986). It is just one particular way of looking at things, a way which privileges detachment, a lack of commitment of the viewer to the object viewed. For some purposes, this can be undeniably useful. But its use in such causes does not make it truer or more real, closer to the nature of things.

Attention also changes who *we* are, we who are doing the attending. Our knowledge of mirror neurons (Rizzolatti et al. 2001) and their function and of the effects of association-priming (Dijksterhuis et al. 2000) shows that by attending to someone else performing an action, and even by thinking about them doing so – even, in fact, by thinking about certain sorts of people at all – we become objectively, measurably, more *like* them, in how we behave, think, and feel. Through the direction and nature of our attention, we prove ourselves to be partners in creation, both of the world and of ourselves. In keeping with this, attention is inescapably bound up with value – unlike what we conceive as "cognitive

functions," which are neutral in this respect. Values enter only through *the way in which* such functions are exercised: They can be used in different ways for different purposes to different ends. Attention, however, intrinsically is a *way in which*, not a thing: It is intrinsically a relationship, not a brute fact. It is a "howness," a something between, an aspect of consciousness itself, not a "whatness," a thing in itself, an object of consciousness. It brings into being a world and, with it, depending on its nature, a set of values.

In experience, these two versions of the world, that of the right hemisphere and of the left, are merged or rapidly alternated in such a way that the subject is not aware of the fact, hence the significance of what we can learn from studying the brain hemispheres: It draws attention to an aspect of the structure of the phenomenal world that otherwise might elude us. The differences that emerge between the two hemispheres in their mode of attending to the world help us to understand better not only the experiential world, but understanding itself.

Some important caveats should be entered at this point. First, it should be clear that these differences are not absolute, but relative, and there is overlap between hemispheres in most respects. Nonetheless, the differences remain consistent and significant. Innate differences are subsequently amplified through experience, since expediency dictates that even a small advantage for one hemisphere in dealing with a certain kind of experience results in its being preferentially used to deal with similar experiences in future. In this way, the hemispheres become further differentiated during development. Second, although general truths are approximate and cannot be taken for rules, they are necessary for understanding. Contrary findings will inevitably exist to any such generalities. However, general truths are no less important for that. The average temperatures in Iceland and Indonesia are clearly very different, which goes a long way to explain the wholly different characteristics of the vegetation, animal life, landscape, culture, and economy of these two regions, as well as no doubt much else that differentiates their "feel" and the ways of life there. But it is still true that the lowest average annual temperature in Indonesia is *lower* than the highest average annual temperature in Iceland – and of course the average temperature varies considerably from month to month, as well as, less predictably, from day to day, and indeed from place to place within each region. This leads to a third caveat: There are interindividual differences, and individuals vary from occasion to occasion.

It is also true that a left hemisphere or right hemisphere on its own cannot be said to do what only a person can do: "believe," "intend," "decide," "prefer," and so on. These and similar formulations should be understood as avoiding the repetition of such cumbersome locutions as "a subject relying on the cognitive faculties of the left [or right] hemisphere believes," etc.

For a full account of the nature of the differences between the hemispheres, the reader is referred to *The Master and his Emissary*: *The Divided Brain and the Making of the Western World* (McGilchrist 2009). However some broad, "headline" distinctions could be made here. It should be understood, nonetheless, that these are very general distinctions, distinctions that ask for qualification at a length that is prohibited here.

The left hemisphere's world requires precision rather than breadth, and aims to close things down as much as possible to a certainty, where the right hemisphere views the broad picture and opens things up to possibility (Ivry and Robertson 1998; Kitterle et al. 1990; Sergent 1982; Robertson et al. 1988; Robertson and Lamb 1991; van Kleeck 1989). The right hemisphere is more capable of a frame shift than the left (Rausch 1977). In focusing on its object, the left hemisphere renders it explicit, and abstracts it from its context (Kinsbourne 1988; Federmeier and Kutas 1999): The right hemisphere is aware of, and able to deal appropriately with, all those things that are required to remain implicit, and are denatured once removed from their context (Alexander et al. 1989; Heilman et al. 1975). The left hemisphere conceives of its object as static, fixed, and atomistic, rather than, as the right hemisphere does, fluid, evolving and interconnected with the rest of the world (Cummings 1997; Bender et al. 1968; Michel and Troost 1980; Müller et al. 1995; Corballis 1996; Corballis et al. 1998). Where the left hemisphere sees disconnected fragments from which the whole picture might be constructed, the right hemisphere sees the whole, the Gestalt, which is more than the sum of the parts, and from which the "parts" have artificially to be determined (Yoshida et al. 2007; Evert and Kmen 2003; Fink et al. 1999; van Kleeck 1989). The right hemisphere is alive to what "presences" to us (to use a Heideggerian term) pre-conceptually; the left hemisphere deals with what is already familiar as a "re-presentation," literally present after the fact (Goldberg 1990; Goldberg and Costa 1981). Where the left hemisphere sees things as general, and disembodied or abstract, the right hemisphere sees them as unique, incarnate, and concrete (Cutting 1997; Kosslyn 1987; Goldberg 1990; Hécaen and Albert 1978). If the left hemisphere is concerned with what can be counted, the quantitative and measurable aspect of experience, the right hemisphere is concerned with the qualitative (Marsolek 1995; Brown and Kosslyn 1993; Kosslyn 1987; Grossman 1988; Cutting 1997; Warrington and McCarthy 1987; Gardner 1974; Bornstein et al. 1969; Bornstein and Kidron 1959; Landis et al. 1986; Bourgeois et al. 1998). One could say that the right hemisphere's world is living, whereas the left hemisphere's world is mechanical and inanimate (Corballis 1998) – for example, only the left hemisphere codes for tools and machines (Gainotti 2002; Perani et al. 1995; Martin et al. 1996; Price and Friston 2002; Mummery et al. 1996; Damasio et al 1996; Cutting 1997).

One might expect, on the basis of the above, that the ways in which the two hemispheres communicated their experience of the world would also differ. It is well known that the left hemisphere alone, in the vast majority of right-handers, is capable of speech in language, but less well known that both hemispheres are intimately involved with language reception – the right hemisphere being especially important for the understanding of an utterance as a whole, in context, with all its nonliteral, implicit meaning (Foldi et al. 1983; Kaplan et al. 1990; Heilman et al. 1975). The right hemisphere therefore plays an important part in the understanding of linguistic utterance, but does not favor language as a way of expressing its perceptions of the world.

By contrast, music is the natural form of expression in the right hemisphere, and the musical aspects of language, including pitch excursions, intonation, inflection,

and rhythm, along with facial expression and body language, all of which are underwritten by the right hemisphere (Blonder et al. 1991; Borod 1993; Breitenstein et al. 1998; Ross et al. 1977; Haggard and Parkinson 1971; Carmon and Nachshon 1973; Wymer et al. 2002; Cutting 1997; Blakeslee 1980), are particularly important in the second-person, "I-Thou" relationship, though they become less important in the third-person, "I-It" relationship. Many contemporary anthropologists indeed argue that music was the primary mode of human expression, and that language emerged from music relatively late in human social evolution, between 80,000 and 40,000 years BC, possibly as a response to the need to communicate explicitly once societies grow beyond a certain point, and have instrumental needs that require referring to things, places, and people not present to the speakers (Milo and Quiatt 1993; Mithen 1998, 2005).

One of the most significant differences between the approaches of the two hemispheres to language is that it is the right hemisphere that is best able to understand metaphor (Foldi 1987; Bottini et al. 1994). There is however some confusion over what is meant by metaphor. Obviously, there is metaphoric content to almost everything we say – language is essentially metaphoric in nature, at the simplest level. In an extensive literature which confirms the right hemisphere's key role in understanding metaphor, there are two studies (Rapp et al. 2004; Stringaris et al. 2007) which have suggested that it is the left hemisphere that is principally involved in the appreciation of metaphor. However, these studies used only overfamiliar or hackneyed expressions. When the metaphor is new or imaginatively demanding, the kind encountered in poetry rather than cliché, it is clearly the right hemisphere that is involved (Faust and Mashal 2007; Foldi et al. 1983; Kaplan et al. 1990). Thus, poetic phrases, such as "rain clouds are pregnant ghosts," are understood by the right hemisphere, while clichés, such as, "babies are angels," are understood by the left hemisphere (Schmidt et al. 2007). Familiar expressions activate the left hemisphere, whereas unfamiliar ones activate the right hemisphere (Bottini et al. 1994; Eviatar and Just 2006; Mashal et al. 2005, 2007). However, it is not the novelty effect alone, but specifically the combination of novelty with metaphorical content that involves the right hemisphere (Mashal and Faust 2008).

Metaphor reveals connections: It relies on openness to the fruitfulness of ambiguity, and the recognition of knowledge which is not propositional in nature but based on relations between forms. In fact, all the aspects of language that are peculiarly important to poetry – not just metaphor, but implied meaning of every kind, irony, connections between ideas not normally approximated, the connotative power of symbols, the music of language (the movement of verse, its ictus, meter, and rhyme) – are all preferentially mediated by the right hemisphere. By common consent over generations, it is poetry which enshrines our profoundest insights into reality, and even philosophers such as Wittgenstein and Heidegger came to believe that philosophical discourse needed ultimately to cede to poetry, as Schopenhauer believed it needed to cede to music. Propositional discourse is limited in its ability to approach ultimate reality. Its very terms take us back, as left hemisphere discourse always does, to the familiar. In Nietzsche's words, language makes the uncommon common.

Additionally, and as might be expected from all the above, the right hemisphere is better able than the left to understand the meaning of symbols with implicit, multiple meanings (for example, the rose, as opposed to the explicit meaning or 1:1 mapping of "red" onto "stop" in the case of a traffic light) (Gloning et al. 1968; Goldberg 1990). In other words, it understands the complex of connotations and how they work to enrich meaning, whether this is in words, or images, or in symbolic enactment, such as ritual of all kinds. The left hemisphere sees in such phenomena only a lack of precision: It sees obfuscation or, at worst, untruth, hence the Enlightenment view expressed by Locke that metaphors were "perfect cheats" (Locke 1690). The right hemisphere is also more able to understand narrative (Ornstein et al. 1979; Mills and Rollman 1980; Swisher and Hirsh 1972; Carmon and Nachshon 1971; Nicholls 1994; Brown and Nicholls 1997; Hough 1990; Schneiderman et al. 1992; Vogeley et al. 2001): The unaided left hemisphere tends to categorize similar episodes of a story together and get them out of sequence, because it does not follow the overall meaning, the way in which a human story unfolds (McNeill 1992).

What does this tell us when we return to the question of how we may avoid the complacent belief that we know all there is to know? Every indicator is that the right hemisphere both grounds our experience of the world, at the bottom end, so to speak, and makes sense of it, at the top end. Broad vigilant attention is primary: Though focused attention may appear to its owner to be under conscious control, in reality, it is already spoken for, since we direct attention according to what we are aware of, and for that we need broad, right hemisphere, attention. Then there is the primacy of wholeness: The right hemisphere deals with the world before separation, division, and analysis have transformed it into something else, before the left hemisphere has re-presented it. It is not that the right hemisphere connects – because what it reveals was never separated; it does not synthesize – what was never broken down into parts; it does not integrate what was never less than whole. The right hemisphere also delivers what is new: It has the primacy of experience. And we must confront the fact that the left hemisphere's most powerful tool, referential language, has its origins in the body and the right hemisphere – a sort of primacy of means. Equally the implicit comes before the explicit. The right hemisphere is more in touch with both affect and the unconscious will, and neurological evidence supports what is called the primacy of affect and the primacy of unconscious over conscious will. Most remarkable of all, some subtle work by David McNeill shows that thought originates in the right hemisphere and is only "worked up" by the left hemisphere (McNeill 1992). For understanding, what is then produced by the left hemisphere needs to be returned to the whole context known only to the right.

The left hemisphere may add – and it adds enormously much – but a return is required to the world that is grounded by the right hemisphere. The left hemisphere's world is a virtual world, one where we are no longer patient recipients, but powerful operators. The values of clarity and fixity are added through the processing carried out by the left hemisphere, making it possible for us to control, manipulate, and use the world. To this end, attention is directed and focused; the

wholeness is broken into parts; the implicit is unpacked; language becomes the instrument of serial analysis and things are categorized and become familiar. In addition, affect is set aside and superseded by cognitive abstraction; the conscious mind is brought to bear on the situation; thoughts are sent to the left hemisphere for expression in words and the metaphors are temporarily lost or suspended, the world being re-presented in a static and hierarchically organized form. This re-presentation enables us to have knowledge, to bring the world into resolution, but it leaves what it knows denatured and decontextualized. For understanding rather than efficient manipulation, there needs to be a process of reintegration whereby we return to the experiential world again. The parts, once seen, are subsumed again in the whole, as the musician's painful, conscious, fragmentation of the piece in practice is lost in the (now improved) performance. The part that has been under the spotlight is seen as belonging to a broader picture; what had to be conscious for a while becomes unconscious again; what needs to be implicit once again retires; the represented entity becomes once more present, and "lives"; and even language is given its final meaning by the right hemisphere's holistic pragmatics.

All the evidence is that the right hemisphere "sees" more than the left hemisphere. Perhaps it is for this very reason that it is more aware of the limitations of its knowledge. In neuropsychological studies, the right hemisphere exhibits a more tentative and self-depreciating style, whereas the left hemisphere is confident about matters of which it is ignorant, and overestimates its capacities (Gazzaniga and LeDoux 1978; Cutting 1997; Rausch 1985; Brownell et al. 1986; Henson et al. 2000; Kimura 1963; Phelps and Gazzaniga 1992; Schnider et al. 1996; Nebes 1974; Drake and Bingham 1985). Moreover, the left hemisphere is better able to inhibit the right than the right hemisphere is able to inhibit the left (Kinsbourne 1993; Oliveri et al. 1999), and transmission is faster from right hemisphere to left than from left hemisphere to right (Marzi et al. 1991; Bisiacchi et al. 1994; Brown et al. 1994; Saron and Davidson 1989). It seems that the cognitive processes of the right hemisphere allow it to appreciate the importance of *what it does not know*, whereas those of the left hemisphere do not permit such insight. And indeed, insight into one's capabilities is largely dependent on the right frontal region (Adair et al. 2003; Bisiach et al. 1986; Feinberg et al. 1994; Meador et al. 2000; Starkstein et al. 1992; Stuss 1991).

Whatever we may mean by the realm of the divine, any apprehension of it would be rendered improbably difficult by a cognitive-perceptual style, the aim of which was to narrow things down to a certainty, and to "recognize" them as examples of something already familiar. More particularly, such a realm would be recalcitrant to thought processes that require explicitness and see truth as a property of a set of syllogisms that exhibit internal coherence. Many – perhaps all – aspects of the human world that give meaning to life present such difficulties. To take just one example, the experience of love in all its many kinds is such that, despite its supreme importance, it cannot be well conveyed in language, especially not in propositional language. Such experiences are part of our embodied life taken as a whole. They can be conveyed best by poetry, or drama, or ritual, or image, or narrative, or music – by means, in other words, that are implicit, embodied, and

contextually rich. They are resonant rather than declarative. The inherent weakness of the analytic method applied to theological matters has been described as "cognitive *hemianopia*" (Stump 2009). This nicely hints that only half the visual field, and therefore one hemisphere's view, is being taken into account. It is not that we are using the proper faculties for the task, though they are half-blind, but that we are using the wrong faculties altogether. Trying to approach the divine using the serial, analytic methods of the left hemisphere is like trying to discover whether the sun is shining by listening for the noise it makes.

At the center of the problem is that although it may be convenient, for some purposes, to pretend that some things are inert, distinct, and atomistic, everything actually exists in a network of relationships with everything else. Some things, such as music, exist only in relationships and yet have the power to mean as much as anything in the world. Music consists entirely of relations, "betweenness." The notes mean nothing in themselves: The tensions between the notes, and between notes and the silence with which they live in reciprocal indebtedness, are everything. Melody, harmony, and rhythm each lie in the gaps, and yet, the betweenness is only what it is because of the notes themselves. Actually the music is not *just* in the gaps any more than it is *just* in the notes: It is in the whole that the notes and the silence make together. Each note becomes transformed by the context in which it lies. What we mean by music is not just any agglomeration of notes, but one in which the whole that is created is powerful enough to make each note live in a new way, a way that it had never done prior to this creation. Similarly poetry cannot be just any arrangement of words, but one in which each word is taken up into the new whole and made to live again in a new way, carrying us back to the world of experience, to life: Poetry constitutes a "speaking silence." Music and poetic language are both part of the world that is delivered by the right hemisphere, the world characterized by betweenness. Perhaps it is not, after all, so wide of the mark to call the right hemisphere the "silent" hemisphere: Its utterances are implicit.

Similarly we know that, while Newtonian mechanics operates at a purely local level, the physical universe is not precise, but probabilistic, that particles separated by a universe may exhibit entanglement, and that the act of observation affects the observed. Although direct comparisons between physics and psychology might appear somewhat far-fetched, the point is a more limited one: Simply that the precision, isolation, stasis, linearity, and predictability of the Newtonian universe is a rough and ready approximation, which works well enough for practical purposes, but is not actually true to the nature of reality, even of all physical reality. Against a space-time background, we model the world as simple two-body systems close to equilibrium, systems which are idealized and only imperfectly representative of the real world: a model that the left hemisphere constructs to enable us to manipulate the world. This representation is opposed to the right hemispheric apprehension of a world that is living, constantly flowing and changing, radically interconnected within itself, and unpredictable – a world that is truer not only to what contemporary physics tells us, but to what attentive reflection on the nature of the experienced world would tell us, were we not conditioned to think of physical reality in terms derived from a model of the universe discredited over a century ago.

In sum, we will never achieve even the starting point for an understanding of the divine by approaching it with the tools of the left hemisphere. Such tools have evolved for purely practical purposes – those of using and manipulating the world expediently. Instead, I suggest we need to approach purported revelations or self-disclosures of the divine principally with the tools of the right hemisphere, the one whose purpose is to be on the lookout for what is not suspected by the left hemisphere, busily engaged as this hemisphere is in the local matter of getting and using. The right hemisphere has evolved to help us be aware of what is going on in the world as a whole, to understand the nature of things in the context of the whole, and to guide our relationship with them. This means that any proposed theology, that is articulated simply in terms of a set of specific propositions drawn from a self-enclosed, abstract model of the world, prizing clarity and internal consistency above all else, risks betraying, distorting, and misrepresenting its subject matter. As the apophatic tradition suggests, such propositions will be inevitably untrue, and stand between us and a purer understanding.

Conclusion and Future Directions

Insights from contemporary neuroscience confirm that images, metaphors, and narratives are indispensable to theological knowledge, not just poor substitutes or intermediate steps in its evolution. A worldview that places supreme value on what is certain, explicit, and literal is likely to misunderstand the nature of theology. At the same time, it will be unaware of what it is that it does not and cannot see. A deeper understanding of the differentiation of the cerebral hemispheres may contribute to debates on the nature of understanding itself.

Neurotheological Eudaimonia 101

Andrew Pinsent

Contents

Abstract
The Aristotelian concept of *eudaimonia*, variously translated as "happiness" or "flourishing," has been a foundational principle of the Western philosophical tradition of virtue ethics. The theology of Thomas Aquinas transfigured the meaning of *eudaimonia*, introducing the concept of "infused" virtues. Rather than being acquired through habituation, these virtues can be understood metaphorically as removing a person's "spiritual autism," enabling second-person relatedness to God. This chapter applies these general principles to examine the everyday role of second-person relatedness in ethical formation, reviewing research into the neural conditions and concomitants of joint attention, and implications for a new understanding of virtue ethics.

Introduction

Anyone who doubts that what is denoted by religious language is widely perceived as having at least some connection to happiness should take a cursory glance at the products of the modern advertising industry. Promotional messages are replete with

words such as "heaven," "paradise," "bliss," and "nirvana," the latter presumably being interpreted by Western minds as heaven with a hint of Eastern promise. Advertisers appear to judge that transient goods, such as health foods or holidays, become more desirable when associated with vaguely religious words, especially those that denote a state of eternal happiness that has proved elusive to unaided human efforts but that features as a goal of many kinds of religious practice. Hence, it is not inappropriate that, in this handbook, the chapter on neurotheology, which applies neuroscience to examine aspects of ultimate human goals within a theological perspective, should be placed close to the section on neuromarketing.

Any study of happiness is complicated by well-known ambiguities, however, such as the need to distinguish what a person seeks subjectively, depending at least in part on her personal history and the "desires of her heart" (Stump 2010) and what is good for the person objectively, a distinction to which advertisers are not always eager to draw attention. Rather than the word "happiness," this chapter therefore adopts the term *eudaimonia*, sometimes translated as "flourishing," taken directly from the *Nicomachean Ethics* (NE) of Aristotle, the "canonical text" (MacIntyre 2007) of the Western philosophical tradition regarding such matters. Besides denoting what everyone seeks, albeit inchoately, the term *eudaimonia* also conveys a sense of objective excellence, especially of what is specific to human life as compared to that of animals and plants (NE I.7, 1097b33-1098a7). For Aristotle, what is most unique about human beings in comparison to plants and animals is their rational principle. Hence his account of *eudaimonia* in the *Nicomachean Ethics* centers on intellectual activity in accordance with virtue or excellence in a complete life (NE I.4, 1098a15-19). This *eudaimonia* is not associated with any specific religious revelation. Nevertheless, it would be misleading to claim that there is no role for the divine, since God is treated elsewhere in Aristotle's work as a first cause and hence as an object, perhaps even the supreme object, of philosophical enquiry in a flourishing life (*Metaphysics* I.1, 983a5-10; XII, 7, 1072b25-30). Moreover, the etymology of the word "*eudaimon*" implies "living in a way that is well-favored by a god" (Kraut 2012), and Aristotle thought that the gods, if they give any gifts to human beings, might be expected to bestow whatever is required for *eudaimonia* on those who strive to be most like themselves, such as philosophers (NE X.8, 1179a22-32).

"Theological *eudaimonia*," as the term is used in this chapter, follows Aristotle's general approach to *eudaimonia* as an activity flowing from virtue, but within the framework of a revealed relationship to the divine that culminates in a state that Aristotle claimed to be impossible, namely, friendship with God (NE VIII.7, 1159a3-5). Specifically, this chapter examines findings in contemporary neuroscience that appear to offer insights pertaining to a new metaphoric understanding of the work of Thomas Aquinas, who developed in the thirteenth century an extraordinarily detailed and influential transformation of Aristotelian virtue ethics. Strictly speaking, this examination is of those embodied experiences that seem to provide the closest everyday parallels to Aquinas's descriptions of theological *eudaimonia*, rather than the purported relationship to God directly. Nevertheless, studies of these parallels are important to evaluate their validity and explore their implications. Moreover, these implications go beyond the theological framework within which

Aquinas's approach was developed, suggesting a new, non-Aristotelian approach to human flourishing generally, one to which contemporary neuroscience is well placed to contribute. Prior to examining the neuroscience, however, it is necessary to review briefly Aquinas's account of *eudaimonia* within his own theological framework and how this differs from the classical and more familiar account of the Western philosophical tradition.

Aquinas on Theological *Eudaimonia*

Aquinas's presents his most detailed account of theological *eudaimonia* in his largest and most famous work, the *Summa theologiae* (ST), which devotes 1,004 articles to the virtues and associated matters, including a generic overview of the various categories in ST 1a2ae qq.55-89 and a systematic account of specific virtues in ST 2a2ae qq.1-170. Much pertinent and insightful material can be found elsewhere, and his scriptural commentaries can be helpful in providing an interpersonal and holistic counterbalance to the fine-grained thematic analysis of many other texts. Nevertheless, Aquinas's mature understanding of the characteristic dispositions of a life that looks toward friendship with God is to be found in all its essential details in the ST.

For many reasons, including Aquinas's admiration for Aristotle, the parallels in their respective accounts, and the pervasive influence of the *Nicomachean Ethics* upon the history of virtue ethics generally, it has long been assumed that Aristotle is the "dominant" though not exclusive voice in Aquinas's treatment of the virtues (McInerny 1993). In recent years, however, a growing body of theologians and analytic philosophers have raised questions about the validity of this interpretation. An indication of the extent of divergence from Aristotle can be seen by comparing the structure of Aquinas's most detailed systematic account of particular virtues (ST 2a2ae qq.1-170) with its counterpart in the *Nicomachean Ethics*. Preceding the four cardinal virtues, the names of which were familiar in pagan antiquity, Aquinas introduces the so-called theological virtues of faith, hope, and "love" or divine friendship (qq.1-46) to make seven major virtues in total. Yet even those virtues that at first seem familiar from classical accounts, such as prudence, justice, temperance, and courage, acquire novelties in the ST. For example, Aquinas adds virtues that are rare in classical writings, such as humility (q.161), and incorporates a great diversity of questions and priorities that are unknown to the *Nicomachean Ethics*. Such issues include, for example, whether backbiting is gravely evil (q.73), whether joy is an effect of devotion (q.82), and whether God should be praised in song (q.91).

At a more fundamental level, however, even the very notion of a virtue in the ST diverges radically from Aristotle's account in ways to which Eleonore Stump, for instance, has drawn attention (Stump 2011). To give a particularly important example, a perfect or true virtue is infused by God rather than acquired by practice according to Aquinas (ST 1a2ae q.55, a.4; q.65, a.3). These infused virtues are unified by the theological virtue of love and can be lost, in the sense of being "cut-off" as virtues, or restored, by singular actions of grave evil or reconciliation rather than by gradual habituation (ST 1a2ae q.71 a.4). What is also puzzling is that

Aquinas's account of these infused virtues is interwoven with other perfective dispositions that are not virtues at all, but dispositions called "gifts" (ST 1a2ae, q.68). According to Aquinas, the gifts are also infused and pertain to the same things as the virtues, but operate in a different manner (ST 1a2ae, q.68, a.4). Whereas a virtue disposes a person to be moved by her own reason, a gift is triadic, disposing a person to be moved by God with respect to some object, in what Aquinas describes as a "union of the soul" with God (ST 1a2ae, q.68, a.1; 2a2ae, q.45, a.3).

Aquinas's account of these virtues and gifts has long proved mysterious, and it is unsatisfactory simply to draw up a catalog of differences from the *Nicomachean Ethics*. The challenge, as Jean Porter has explained, is that "the infused virtues function in a way that is significantly different from the way in which the acquired virtues function, so much so that they can be described as virtues only in a carefully qualified sense" (Porter 1992). The deeper problem is that if language is to have any agreed meaning, this meaning plausibly depends on being able to associate words with embodied experience by means of metaphor, an association given some additional credence from recent work in neuroscience (McGilchrist 2009). In the Western philosophical tradition, however, Aristotle has associated the term "virtue" with the experience of habituation, comparable to practicing a sport or musical instrument (NE II.1, 1103b6-22), an experience that is irreconcilable with Aquinas's claims about the infused virtues. If it is possible to understand properly what Aquinas means by an infused virtue, an alternative embodied experience is required. Based on Aquinas's detailed descriptions of the virtues and gifts, it is arguable that the appropriate experience is what experimental psychologists today call "joint attention" (Pinsent 2012), an aspect of social cognition that involves a "sharing an awareness of the sharing of the focus" on some object with another person, something that often entails "sharing an attitude towards the thing or event in question" (Hobson 2005). The infused dispositions that Aquinas describes can be understood as putting a person into a joint attention relationship with God. This joint attention relationship forms a person's attitudes to all kinds of other matters in ways that will often be different to what these attitudes would be in the absence of this relationship.

From this interpretation, there is another metaphor for the effect of the infused dispositions described by Aquinas. Some scholars have suggested that joint attention may be the root experience for understanding what it means to relate to a person specifically as "I" to "you," and for expressing such relatedness in language (Heal 2005; Roessler 2005). Moreover, the study of autistic spectrum disorder has given some empirical weight to this association, insofar as a diagnosis of autism in children is often associated both with a deficiency of engagement in joint attention (Wimpory et al. 2000) and with difficulties in learning the correct use of second-person forms of grammar (Tager-Flusberg 1994). On this basis, another way of understanding Aquinas's account of the infused dispositions is that they enable specifically second-person relatedness to God, removing what could be likened to an innate *spiritual autism* of unaided human nature from the divine perspective. From this perspective, the question the Lord God directs to Adam after the narrative of the Fall in the Garden of Eden, "Where are you?" (Gn 3:9), and perhaps also in part the set of rhetorical questions directed by the Lord to Job,

"Where were you?" (Jb 38-41), articulates a loss of second-person relatedness with human beings that the infused virtues and gifts of theological *eudaimonia* are intended to restore.

This interpretation in terms of second-person relatedness should of course be treated as a metaphor, like the removal of physical blindness has long been used as a metaphor for intellectual enlightenment. Nevertheless, this relational metaphor has considerable explanatory power in unifying what would otherwise appear as rather peculiar and ad hoc claims about theological *eudaimonia*. For example, as noted previously, Aquinas claims that the infused virtues, unified by the theological virtue of love, can be lost, in the sense of being "cut-off" as virtues, or restored, by singular actions of grave evil or reconciliation, a claim that makes no sense at all from a traditional understanding of virtue in terms of habituation. If, however, the goal of the virtues is divine friendship, a state of harmonized second-person relatedness, then it is easier to see how a relationship can be betrayed or restored by a single action. Following a betrayal and concomitant loss of relationship, acquired good habits of daily life will not suddenly vanish, but they will cease to be virtues that are able to contribute to a state of second-personal flourishing with the other person, at least until the relationship is restored (Pinsent 2012). For this reason, wrongdoing in this worldview is also "sin," with the connotations of betraying a second-person relationship that is often described using the language of "covenant" rather than contract.

The account presented above is a theological one, and presupposes the existence of supernatural elements such as a personal and loving God who is willing and able to infuse dispositions into persons that enable them to relate to God in a second-personal way, culminating in friendship. Nevertheless, it is not difficult to see that the general framework of Aquinas's account has far broader implications. In everyday life, the development of virtues may be dependent on second-person relatedness in ways that are opaque to a traditional Aristotelian analysis. For example, a commonplace experience is that children first acquire temperate behavior with respect to food and drink not through selecting a virtuous mean established by practical wisdom, but generally by some kind of second-person interaction, such as a game, with a parent or caregiver (Werle et al. 1993). Such considerations highlight the need to examine further the association of second-person relatedness and character formation and, in particular, to examine what neuroscience can contribute.

Second-Person Relatedness and Social Neuroscience

Aquinas's account of how a person's behavior is shaped by a relationship to a personal God is radical as much for what it excludes as for what it includes. There is no trace of reasoning along the lines of the following, "I desire *P* in order to flourish. If I do *Q*, God will grant me *P*; therefore I do *Q*." More generally, God is not simply a means to an end and does not enter into Aquinas's account simply as some all-powerful third-personal or impersonal agent capable of adding or subtracting various goods of human flourishing. Instead, true flourishing consists

in a perfection of second-person relatedness, with God culminating in divine friendship. Across the spectrum of what is encompassed by the field of social neuroscience, what is therefore of greatest relevance to this account of flourishing is whatever pertains specifically to second-person relatedness in ordinary and everyday human relations. As noted previously, such relatedness is not simply awareness of a person or interpersonal interaction generally, but has been described as a shared awareness of the sharing of focus with another person, which often involves sharing an attitude toward the object of shared attention. The object of the attention may be a physical object, a shared activity or possibly, by perceived cues, an abstract idea. Such an interaction may be almost too slight to register, as in a momentary glance of recognition or a smile between strangers, or profound and sustained with a lifelong friend. Nevertheless, across the range of possible situations, the experience of joint attention implies a sense of the other person being, in some sense, present to oneself, a presence that does not appear necessary when simply thinking about someone, or thinking about what another person is thinking about. Moreover, the subjective experience of joint attention is typically described as a "meeting of minds" with the other person (Eilan 2005).

Framed in these terms, it is possible to begin to sift the most relevant findings available from social neuroscience, but caution is needed in identifying and describing the most appropriate phenomena. For a start, there is an influential school of thought in contemporary philosophy that holds that the subjective experience of a thing is irreducible to knowledge about a thing, regardless of the detail of that knowledge (Nagel 1974), and experience of a person as a person is plausibly among those things that are most irreducible. In social neuroscience, however, this distinction sometimes risks being obscured a priori by much of the language in which knowledge of persons is expressed. For example, it is commonplace to describe the way in which one being-with-a-mind identifies and relates to another being-with-a-mind in terms of "Theory of Mind" (ToM), reference to which was made in 1 % of all academic publications in psychology that referred to infants or children in 2003 (Reddy and Morris 2004). Although it is true that ToM may be interpreted as "more like a loose coalition than a unified movement," the mere label of a field of research or a "folk psychological" concept (Costall and Leudar 2004), the word "theory" almost invariably invokes in us embodied experiences connected with simplified, formal, and quantitative representations of the world that are inherently objective rather than subjective. Moreover, the term "theory" is typically employed to describe situations in which what is being theorized about is objective and does not need to be personally present. Even if the term in fact turns out to be an appropriate one, it therefore seems prudent to focus on those interpersonal phenomena that seem at first to be most *unlike* one person theorizing about the mind of another, if the aim is to discover what, if anything, is most distinctive about second-person relatedness.

The remainder of this section therefore focuses on those aspects of social neuroscience involving interpersonal relatedness in situations of mutual presence that, for one reason or another, appear closer to "thinking with" rather than "theorizing about" the other person. To give some examples to clarify this

emphasis, Colwyn Trevarthen has noted the many ways in which a responsive mother "dovetails" with her infant (Trevarthen 1979), and musicians playing in harmony in an orchestra also seem to be thinking with rather than theorizing about one another. Something like this distinction has also made by Hein and Singer's proposed two pathways for understanding another person's mind, namely, empathy and embodiment of another's emotions versus theory of mind, mentalizing, or cognitive perspective taking. Moreover, they also claim that these distinct modes of understanding involve activation of different areas of the brain (Hein and Singer 2008), although the extent to which a precise differentiation is possible or meaningful is a matter of debate (Adolphs and Janowski 2011). What can be said, however, is there is growing evidence of distinct modes of understanding of the minds of others, at least one of which can be described broadly as thinking with a person.

So what kinds of phenomena in social neuroscience are most appropriate to this "thinking with" another person in second-person relatedness, especially insofar as the latter experience, may serve as a metaphor for theological *eudaimonia*? Philosophers from at least the time of Aristotle have highlighted how any intellectual operations that give rise to human action must have cognitive and affective aspects. Such aspects may be practically synchronous and inseparable, with the affective aspects being far easier to detect than cognition alone by means of behavioral or physiological changes. The famous "Eureka!" moment attributed to Archimedes would not have been so dramatically obvious to his fellow citizens if he had merely understood the answer to the problem set him by Hiero of Syracuse without also expressing his joy in an unconventional way. Moreover, proponents of what is sometimes called "common coding theory" have emphasized how some of the neurological correlates of thought and action may be practically inseparable (Sperry 1952). Certainly, the direction of causation between thought and action is not wholly one way, shown by the way in which the disruption of human premotor cortex impairs speech perception (Meister et al. 2007) and a wide range of research showing how mental simulations take place when processing information (Niedenthal et al. 2011). Furthermore, consideration of the many human actions that happen without conscious reflection, for example, swift responses to sudden threats, or habitually trained "lower level" actions such as the movement of fingers on a keyboard, along with much neuropsychological research on automatic brain responses, underlines how the mental processes that give rise to human action are much broader than those we reflect on consciously (Libet 1985). Nevertheless, if intellectual operation, whether conscious or not, is properly a cause of any human action, it is hard to circumvent the need for such operations to have cognitive and affective aspects, respectively, the cognition of a thing and attitude toward the thing as good to pursue or avoid. Moreover, recent research has suggested that cognitive and affective aspects of mental activity are even dissociable under certain conditions (Shamay-Tsoory and Aharon-Peretz 2007; Völlm et al. 2006; Hynes et al. 2006). Hence also one would expect "thinking with" operations of second-person relatedness, if they are to be the basis of any human action, to have both cognitive and affective aspects.

Second-person relatedness, however, is complicated by the fact that "thinking with" situations have a triadic person-person-object form. Hence, if there are dedicated processes in mental activity that are attuned to this kind of relatedness, one would expect some such processes to be directed to the object of shared attention, with others dedicated to establishing, monitoring, and maintaining union with the second person. Such processes would divide roughly along the following lines: (1) cognition of a second person; (2) cognition of harmonization with a second person, and a pre-disposition to favor such harmonization; (3) joint cognition of an object; (4) joint stance toward the object, where "stance" is "a conative attitude prompted by the mind's understanding" (Stump 2011). Note that in actual joint attention, the second person may only enter into the periphery of personal experience. The following paragraphs list some examples of phenomena pertinent to these processes in social neuroscience.

Cognition of a second person: Both the existence and importance of specific second-person cognition are strongly indicated by the rapid ability of newborn infants to identify persons from the range of beings that they first encounter, and by their interest in faces and the imitation of facial expressions (Meltzoff and Moore 1977). On the latter observation, it should be noted that a special connection between face cognition and second-person relatedness has long been drawn by theologians, artists, and philosophers in the tradition of Martin Buber, Emmanuel Levinas, and their successors. More recently, there has been a great variety of accumulating evidence for specific neuronal activity correlating with face cognition, as compared to the cognition of non-facial objects (see, for example, Thompson 1980; Yin 1969; Assal 2001; Bodamer 1947; Farah et al. 1995; Freiwald et al. 2009; Perrett et al. 1985; Rolls 2007). The role of the human face in typical second-person relatedness has also been highlighted by deficits of face cognition in cases of autistic spectrum disorder (Klin et al. 1999) and, conversely, some of the symptoms of autism in cases of prosopagnosia ("face-blindness") (Dalrymple et al. 2012). Face cognition is not the only channel for second-person relatedness, however, as suggested for example by evidence of neural processes that correlate with hearing the sound of human voices (Belin 2011).

Cognition and enjoyment of harmonization with second person: A wide range of evidence suggests that there are neural processes dedicated to the ability to cognize and enjoy harmonization with a second person. The rapid imitation by newborn infants of the facial expressions of adults, noted above, is not only evidence of face-cognition abilities but is also an example of an innate and early disposition toward such harmonization. Moreover, infants as young as 3 months shift their visual attention in the direction toward which the eyes of an adult face turn (Hood et al. 1998). This ability to engage in joint attention appears at roughly the same time, or perhaps even slightly precedes, an infant's first-person ability to flexibly orient attention to objects in her environment (Kirwan et al. 2011). The cognition and enjoyment of harmonization with a second person will typically continue throughout life, often at a level that is subliminal to more overt communications such as speech. To give some of many examples, the "chameleon effect" and the fact that being imitated increases liking (Chartrand and Bargh 1999) may be another

symptom of the way in which we are predisposed toward a harmonization with others. In addition, there is evidence of an innate distaste for situations in which second-person relatedness is not quite right, is interrupted or mistaken. For example, human beings have a negative emotional response to simulations in which something is almost but not quite like a second person, a problem known to animators as the “uncanny valley” (Mori 1970; MacDorman and Ishiguro 2006). What may also be of relevance is the fact that human beings are predisposed to pay a high price for second-person relatedness, even if such relatedness is not fully actualized. A possible example is the way in which many subjects in prisoners’ dilemma games prefer mutual cooperation even though it is in their self-interest to defect whatever the other player does (Kiyonari et al. 2000). A relative lack of mutual cooperation, and a more utilitarian approach to such games, tends to be associated with states in which cooperative inclinations have been inhibited or suppressed, either by brain lesions (Ciaramelli et al. 2007; Koenigs et al. 2007) or possibly by long periods of training in economics (Frank et al. 1993).

Joint cognition of an object: The issues of most conceptual interest under this heading are: (i) whether or not there is a shift in the nature of cognition when shifting from individual attention to joint attention, as opposed to a mere change in external factors such as learning where to direct one’s attention; and (ii) whether joint cognition is in principle reducible to psychological states of an individual which do not already imply such cognition with a second person; or else whether joint cognition is a “primitive phenomenon” (Campbell 2005). In regard to such questions, a promising discovery has been the mirror neurons, which have been directly observed in primate and some other species such as birds, to fire both when the animal acts and when the animal observes the same action performed by another (Di Pellegrino et al. 1992; Gallese et al. 1996; Ferrari et al. 2003). Such operations are often expressed in terms of “simulating” some cognitive process of another being by the activation of parallel cognitive processes that, if carried into action, would produce similar behavior. Even the term “simulation” may be subtly misleading, however, since this word in daily life typically denotes a replication based on abstract models of reality. By contrast, the immediacy of the mirror neuron activation and the fact that such activity is found in a wide spectrum of nonhuman animals suggests that this replication is a primitive phenomenon that does not depend on explicit or effortful reasoning. Although the operation of mirror neurons in human beings cannot be observed directly, there is strong indirect evidence for them in the human brain (Iacoboni 1999). Moreover, the mirror neuron areas in human beings are not simply involved in registering actions, but activate in specific ways upon the observation of intentional actions, such as grasping an object (Iacoboni et al. 2005). Nevertheless, claims that mirror neurons explain “action understanding” probably go beyond what evidence can support (Hickok 2009), not least because of the temptation to mix the language of psychological powers such as “understanding” with those of the neural conditions and concomitants for the exercise of such powers (Bennett and Hacker 2003). Perhaps the best that can be said is there are promising candidates for at least some of the neural conditions and concomitants

required to permit an exercise of joint cognition that is "primitive," both in the sense of being irreducible and of playing a foundational role in early cognitive development.

A joint stance toward the object: There is a wide range of evidence supporting the principle that a stance toward some object of joint attention is different to what the stance would be in the absence of such relatedness, even when it is the object, and not the other person, that is the direct focus of attention. An everyday example is joint attention with infants, in which the infant displays a preferential interest in the object that the caregiver is also attending. Particular tones and melodic contours of what is sometimes called "motherese" plausibly become associated with a particular stance long before infants become sensitive to the segmented words of language (Donald 2001; Falk 2009). The emotional content communicated in this way arguably helps to foster the remarkable ability of human infants to show recognition of intentions from vocal utterances, a point of divergence from apes that also contributes to the acquisition of language (Bloom 2000; Gärdenfors 2003; Kuhl 2011; Tomasello 1998). Yet even ordinary language between adults also involves much more than propositional speech. The distinction and importance of prosody and other nonverbal communication has been shown in many ways, for example, by the effects of damage to the right hemisphere's perisylvian region correlated with an impaired ability to express emotion using prosody (Heilman et al. 2004). Such nonverbal communications, which cannot easily be abstracted from the context of a specific "I" communicating with a specific "you," have reemphasized the need to think about language not simply in terms of objective symbol use and organization, but as a communicative interaction between persons (Nusbaum 2011). These findings are consistent with a general account of nonverbal communication beginning in infancy with situations of joint attention and remaining important in adulthood. Among its other consequences, such communication, in effect, invites and enables a second person to share a stance toward something.

Drawing these observations together, there seems to be growing evidence to support the view that second-person relatedness is irreducible and important to human flourishing, that it is intimately associated with joint attention, and that there are strong candidates for at least some of the neural conditions and concomitants that enable joint attention in daily life. Do such discoveries have much bearing on ethical issues, however, such as the formation of virtues? Sharing a simple stance of attraction or repulsion toward a physical object or activity may indeed communicate to another person that the object is or is not good, but the objects of ethics tend to be abstract matters, such as justice or temperance. Can second-person relatedness also assist in forming a moral stance and hence cultivate virtue? This principle provides the proposed metaphoric understanding of Aquinas's account of theological *eudaimonia*, and therefore, the question is important to both philosophy and theology.

Researchers in social neuroscience often address pertinent issues using rather different terminology to that of virtue ethicists, but there are some experiments that may help to shed light on this question. Although such research is still new, there is

accumulating evidence that babies have a surprisingly sophisticated moral awareness, with 6- and 10-month-old babies at Yale University's Infant Cognition Center preferentially selecting "nice" over "naughty" puppets (Bloom 2013). What is significant about such findings is that babies inhabit a world in which their awareness of persons is presumably almost entirely second-personal, since it seems unlikely that they are able to carry out moral reasoning about persons in an abstract manner, and it has also been argued that they do not have properly formed first-person awareness until some time in their second year (Ferrari and Sternberg 1998; Keenan et al. 2003). So second-person relatedness is arguably already shaping moral awareness in the first year of human life. Supporting evidence for this conclusion comes from the difficulty of inculcating even basic virtues of self-preservation, such as the desire to eat in a temperate manner, in situations in which second-person relatedness is inhibited (Legge 2002).

Among adults, it is generally harder to disentangle the effects of second-personal relatedness from the conclusions of abstract moral reasoning. Nevertheless, there is some evidence that a moral stance is influenced, often in a sublimal manner, by the presence of a second person at the periphery of awareness, or even just a representation of a person such as a picture of a pair of eyes (Bateson et al. 2006). Moreover, even some choices that appear to involve only a single moral agent sometimes replicate patterns of second-person relatedness. As has been verified experimentally many times, "the act of breaking one's resolve can lead to a general dys-regulation of appetitive behaviour" (Wagner et al. 2011; cf. Herman and Mack 1975). These findings appear to be consistent the view that a personal moral resolution functions rather like a derivative of a covenant with a second person that, once broken, requires an act of reconciliation and a new resolution before a virtuous pattern of life can be resumed.

Conclusion and Future Directions

As the brief outline above has attempted to show, an account of moral theology developed by a Dominican friar in the thirteenth century has surprising relevance to contemporary work on the virtues and human flourishing, an approach that organizes many findings of social neuroscience around the principle of second-person relatedness. For a life shaped by a similar theological outlook today, this work may help to reinforce the value of specifically second-personal aspects of religious practices, such as the depictions of holy faces in sacred art, the use of music in shared liturgy, and the communication of religious teaching by stories of persons as well as propositions and rules. An analytically trained mind may be tempted to overlook the value of such practices, but they are not adventitious to a worldview in which theological *eudaimonia* is second-personal and culminates in divine friendship. Beyond its theological origins, however, there is hope that such research may help to contribute to a broader "Copernican Revolution" in the understanding of virtue ethics in the twenty-first century, "a shift in the locus of explanation from the first-person to the second-person perspective" (Pinsent 2012).

Section XXI

Neuromarketing

Ethics of Neuromarketing: Introduction

102

Edward H. Spence

Contents

Abstract

This section examines ethical concerns that arise in neuromarketing. In particular, the entries in this section discuss ethical issues with regard to *brain privacy* (Steve Matthews) specifically, "the collection over time, and aggregation of private brain information, where the target loses control over its ownership and distribution" (Steve Matthews); the ethical concerns that Direct Consumer Advertising of Prescription Pharmaceuticals (DTCA) involving implicit persuasion through evaluative conditioning has "deleterious effects on autonomous agency" and that it has a negative impact on the "wider doctor-patient relationship" (Paul Biegler, Jeanette Kennett, Justin Oakley, and Patrick Vargas); and in addition, the Introduction of this section (Edward H. Spence) briefly examines how the association of brands with values raises ethical concerns relating generally to some of the ethical issues examined by the aforementioned authors in this section.

Assessing the Ethical Concerns of Neuromarketing

As Steve Matthews outlines in his chapter of this section, ▶ Chap. 103, "Neuromarketing: What Is It and Is It a Threat to Privacy?," peer-reviewed published articles on neuromarketing jumped from nothing in 2000 to 250 published articles and 150 neuromarketing companies in 2010 (Matthews, p. 9). Although there has been a sharp increase in neuromarketing publications and neuromarketing companies, Matthews argues that neuromarketing practices as such do not raise any special ethical worries or novel ethical concerns that were not previously present in product marketing and advertising.

For Matthews, the main ethical concern in neuromarketing relates to privacy and, in particular, brain privacy. According to Matthews "worries about brain privacy, seem, prima facie to be justified, but on closer analysis, fall away." He does, however, cautions that "a residual threat to privacy does remain: the collection over time, and aggregation of private brain information, where the target loses control over its ownership and distribution" (page 1628).

In my article "The Advertising of Happiness and the Branding of Values" (Spence 2013; Spence and Van Heekeren 2005) I am led to a similar conclusion with regard to the ethical concern raised by the implicit and explicit association of brands with values in advertising. Namely, that it is not the piecemeal association of brands with values that is the ethical problem but rather the widespread, systemic, and cumulative association of brands with values that is of ethical concern, that is, the concern that over time that association de-values and degrades aspirational social values such as *friendship* and *happiness* among others, by reducing them to the mercantile and consumer value of brands.

The central ethical problem Matthews focuses on in his chapter is that of brain privacy. Matthews' main claim for which he argues with great clarity and compelling arguments on the basis of the "principle of proportionality" (a philosophical principle also used efficaciously by Aristotle in his *Nicomachean Ethics*) is that "worries about brain privacy seem, prima facie, to be justified, but on closer analysis, fall away." He cautions, however, that "a residual threat to privacy does remain: the collection over time, and aggregation of private brain information, where the target loses control over its ownership and distribution."

Matthews also quite rightly draws attention to the effectiveness of certain communication strategies that operate at the interface of the internal brain environment of consumers (their brain states) and the external shopping environment in which they exercise their purchasing choices and make their purchasing decisions. As Matthews argues, empirical studies have shown that "Emotionally charged advertisements are more effective in generating memories of the brand. This makes plausible the view that neuromarketeers (*qua* marketers) are interested in brains-in-the-market; and the brain, hitherto inaccessible to market producers and advertisers, now takes its rightful place in the model to complete the picture."

Matthews' argument about the effectiveness of certain communication strategies used by neuromarketers and advertisers to generate emotionally charged advertisements that enhance memory retention and attention for brands, appears to dovetail

and lends empirical support to my own ethical concern regarding the association of brands with aspirational values. One such communication strategy, the association of brands with values, which I discuss in detail in my aforementioned article (Spence 2013), does seem prima facie at least to be effective in generating a positive emotional response or pro-attitude to particular brands through the association of those brands with particular aspirational values such as friendship, love, or happiness.

In their chapter of this section, Paul Biegler, Jeanette Kennett, Justin Oakley, and Patrick Vargas (for ease of reference Biegler et al. henceforth) focus on ethical problems that arise with regard to *Direct to Consumer Advertising of Prescription Pharmaceuticals (DTCA)*. According to them this is a controversial practice that is only permitted in the United States and New Zealand. The focus of their discussion is implicit persuasion through evaluative conditioning, which they argue has "deleterious effects on the autonomous agency that DTCA viewers bring to medicine choices, and on the wider doctor patient relationship" (page 1647). Their conclusion is that "There are good reasons to suppose that evaluative conditioning leads to more positive attitudes toward the advertised drug, and that such attitudes encompass inflated beliefs about drug safety and efficacy. Of grave concern, however, *is that the positive imagery deployed to produce such conditioned beliefs bears little substantive relationship with properties of the advertised drug* [emphasis added]. Given the materiality of these drug properties for people contemplating pharmacological treatment, such an unreliable influence on belief will likely undermine their justification, and antagonize the autonomy of resulting medical decisions." (Biegler et al., page 29)

The segment emphasized in italics in the above quoted passage is meant to draw attention to similar findings in my article (Spence 2013), albeit from a conceptual analytic perspective as compared to these authors' empirical findings. In that article, I raise similar concerns but specifically with regard to the association of brands and values. Such an association I argue is ethically problematic at the very least, because it is misleading and inaccurate at best and at worst false and deceptive as brands in themselves do not have the inherent characteristics of the aspirational values attributed to them by the advertising association to consumer products.

In their chapter, Biegler et al. concentrate their attention on implicit persuasion used in DTCA where individuals are unaware of the persuasive process being used. Although the persuasion is supraliminal and the resulting attitude achieved can be reported by the individuals subjected to this kind of persuasion technique, the mode of persuasion itself remains hidden (page 1649). They offer a nice example of this type of supraliminal persuasion from advertising. In advertising, they point out, "images of happy smiling people may be used to condition positive attitudes toward a novel product, for example, a new brand of shampoo" (page 1650). I would add that the same technique is used in the association of brands with values to which I have referred to earlier (Spence 2013). To the extent that I am right one would be justified in saying that the association of brands with values is a type of supraliminal persuasion where the resulting attitude can be reported by the individual but whose mode of persuasion remains hidden. Prima facie at least the empirical evidence

cited by Biegler et al. in support of their arguments for ethical concerns with regard to this type of implicit persuasion lends support to my own conceptual analytic findings in my article (Spence 2013) where I raise similar ethical concerns for the association of brands with values.

Based on various empirical studies which the authors examine in meticulous detail, Biegler et al. conclude that "There are strong reasons to hold that evaluative conditioning in DTCA, and other implicit persuasive techniques, comprise unreliable belief forming mechanisms that foster unjustified beliefs about pharmaceuticals."

According to the authors, this raises concerns about the overall effect that these techniques have on the autonomy of individuals subjected to these techniques, which may result in the "corruption of the deliberative process" in the choices they make (page 1654).

One final issue of great importance raised by the authors is skepticism about the role of rational agency itself in decision-making, which seems supported by various empirical studies cited by the authors, which show that, "notwithstanding our beliefs to the contrary, individuals really have little idea of why they make the choices they do" (page 1656). At first glance, this seems to undermine the concerns raised by the authors concerning the effect on autonomy and agency by the implicit persuasion techniques discussed in their chapter. However, although the authors accept the findings of the empirical results concerning the role of rational agency in decision-making, they quite rightly and perspicuously respond to such skepticism by pointing out that "evidence about the limits of rational agency and the need to counter irrational assessments of risk made by patients exposed to DTCA cannot constitute an argument for permitting implicit persuasion in DTCA. Rather it seems to constitute an argument against permitting DTCA at all" (page 1658).

Conclusion and Future Directions

Together the two chapters in this section raise measured but serious ethical concerns about the role and deleterious effects of neuromarketing on brain privacy, as well as concerns about the role of implicit persuasion through evaluative conditioning as used in Direct Consumer Advertising Pharmaceuticals (DTCA) and its related negative impact on the wider doctor-patient relationship. In addition, within the context of those concerns, I have raised related ethical issues concerning the general problem concerning the systemic and widespread advertising practice of associating brands with values, which I have argued can be seen as a general implicit persuasion technique through evaluative conditioning. Together these articles provide novel research that raise ethical concerns about neuromarketing techniques that should be taken seriously. Further empirical research to evaluate how the association of brands with values degrades those values would be useful in assessing the impact it has on our social perception and appreciation of values. As well, it would also be very useful to relate that empirical research on brands and values to the type of empirical research on neuromarketing referred to in the chapters of the authors in this section.

Neuromarketing: What Is It and Is It a Threat to Privacy? 103

Steve Matthews

Contents

Abstract

This entry has two general aims. The first is to profile the practices of neuromarketing (both current and hypothetical), and the second is to identify what is ethically troubling about these practices. It will be claimed that neuromarketing does not really present novel *ethical* challenges and that marketers are simply continuing to do what they have always done, only now they have at their disposal the tools of neuroscience which they have duly recruited. What will be presupposed is a principle of proportionality: marketing practices are morally objectionable commensurate with the degree to which they impugn the moral sovereignty of market actors. With this principle in mind, it is important to consider the literature which is skeptical about the potential for

S. Matthews

neuromarketing to be successful. If its claims are overblown, as will be suggested, then the ethical threat neuromarketing is said to pose can be viewed also as overblown. An area that has worried many is that neuromarketing poses a threat to brain privacy, and so an analysis will be given of the nature of this threat, given the principle of proportionality. It will be argued that worries about brain privacy seem, prima facie, to be justified, but on closer analysis fall away. However, a residual threat to privacy does remain: the collection over time, and aggregation of private brain information, where the target loses control over its ownership and distribution.

Introduction

The literature on neuromarketing variously describes it as the "...application of neuroimaging techniques to sell products" (Lee et al. 2007, p. 200), the use of neuroscience to gain "...powerful insights into the human brain's responses to marketing stimuli" (Murphy et al. 2008, p. 293), "...the application of the findings from consumer neuroscience within the scope of managerial practice." (Hubert and Kenning 2008, p. 274), and "...applying the methods of the neurology lab to the questions of the advertising world." (Thompson 2003, p. 53). Although somewhat helpful in landing us in the right territory, these definitions are loose and sufficiently non-coextensive for neuroethicists to be rightfully dissatisfied. (To be fair, each of the writers above sought to identify their subject matter in quick and dirty terms). Part of the motivation here is to become clearer about the nature of neuromarketing in order to assess that practice from an ethical standpoint; a set of defining conditions for neuromarketing will not be proffered, but rather, the intention will be to provide some description of the institutions and practices that are both presently associated with neuromarketing, as well as those that seem a reasonable possibility in the near future, so as to evaluate their ethical significance.

Definitions

The term "marketing" refers to those processes or activities that facilitate the movement of a product or service by focusing on its value in an exchange setting. In that broad sense, it refers to the design and production of goods and services, their distribution and pricing, and the communication strategy set forth in the market. Thus construed, advertising (the communication strategy) forms a subbranch of marketing. Advertisers communicate a message about a product or service ultimately to increase sales or market share. A marketer need not be narrowly focused on the persuasive aspect of a business. For instance, a marketing department of a company typically works in close proximity with company operations concerned with product design or content (Kotler and Keller 2012; see part 5). Currently, neuromarketers are less able to retrieve neuroscientific data in natural settings and tend to test subjects in the lab, typically for responses to such things as brand choice, pricing, product design, the

buying environment, responses to different kinds of advertisements, what grabs the consumer's attention, etc. This is neuromarketing devoted to *understanding* the brain-mind of the consumer, in contrast to a practice in which they might seek more directly to influence the consumer. The intention of neuromarketers to develop this capacity (securing brain response data in the market, in real time) raises an important strategic question for them: at which point, along the chain from design to use of a product, should they extract this data? (The place they seem most interested in, as discussed below, is point of sale). The ethical questions here will be around the invasiveness, and transparency, of this strategy.

Neuromarketers, then, although almost wholly devoted to recruiting neuroscience techniques to identify features of the consuming mind for market advantage, may also in the future engage in the business of persuading and influencing directly. Neuromarketers who aim to influence (neuroadvertisers let's say) would be more at risk for ethical breaches because they are engaged in advertising behavior that is inherently morally risky. As described below, this consists in boundary crossings, nondisclosure, and targeting of customers. For neuroscience that seeks only to identify features of consumer cognition, these risks subside. Neuroscientists here conceive of themselves as generating knowledge about the mind of the consumer, and marketers may, and do, latch onto this research. These neuroscientists are of course not engaged in marketing, and the distinction between research and this kind of engagement is clear enough by observing the place from which they work: the academy. (Things are less clear when qualified neuroscientists are employed by neuromarketing companies or form independent private consultancies themselves). Almost all neuroscientists who work in the academy and who research marketing questions do so not to the exclusion of other related interests; they would be dismayed were they referred to as "neuromarketers." A neuromarketer, in my usage, is a person with an interest in applying neuroscience ultimately to derive a commercial outcome. A neuroadvertiser is a kind of neuromarketer, one whose role is less remote from the shop floor than a neuromarketer who is not a neuroadvertiser.

(It should be recognized that these distinctions are impure: there may be cases where an individual occupies a dual role, as marketer and as academic, or whose role is morally ambiguous (say when the research is funded by a private corporation). These cases raise a familiar ethical question for such a stakeholder: are commercial interests in this research contaminating its intellectual purity? Notwithstanding its importance this question will not be pursued here).

Neuroadvertising: A Hypothetical Example

Consider an elaboration of a hypothetical example of neuroadvertising (Wilson et al. 2008). Although most of the buzz in neuromarketing has been, and still is, around fMRI scanning, other technologies may be used, including Quantitative electroencephalography (QEEG) and Magnetoencephalography (MEG). QEEG, say its advocates, "...is simpler and less expensive to use and enables recordings to be made in a wide range of natural environments" (Lewis and Brigder 2005, p. 37).

Nevertheless, QEEG is still somewhat cumbersome. So let us imagine the currently impossible situation of a technology that neuroscreens subjects remotely and potentially secretly. Marketers may, then, envision the use of such a thing in something called the "intervention" phase of a persuasion model of neuromarketing (Wilson et al. 2008, p. 395). In designing a large department store, a marketer might imagine the impact of the stimuli on the inchoate consuming brain as it enters the store, motivated as the marketer is to maximize the amount of money to be shifted from the target consumer's bank account to the storeowner. The marketer must, therefore, understand the impact of these stimuli and design accordingly. To effect this, say Wilson et al. (2008, p. 398), "...retailers may neuroscreen potential customers upon entering, registering reactions to what they see, hear, feel, touch, taste, and/or smell, and combining these measurements and outcomes with previous readings based on earlier visits."

In this example, the marketing aim is to use neuroimaging remotely and directly as a tool to smooth the progress of the transaction in real time and in real commercial space. What is ethically bothersome about such a practice? The all-important distinction is of course between the case where full disclosure takes place and cases where less and less disclosure is evident. In the case in which no disclosure takes place, three elements of ethical relevance stand out. First, this is a clear case in which the seller is manipulating the environment to sell goods. Is that ethically objectionable? Is it sui generis? The answers, surely, are "no, not really" and "no, it is standard practice – it is well known as part of the institution that constitutes market practice...buyer beware!" The second is that this is a case where the consumer's lack of information about the retail environment prevents her from consenting to aspects of the transaction there. This is more serious because the seller is now operating with an unfair advantage given that the buyer's natural competence to operate in that situation has been undermined without his permission.

A third element is more serious yet. An ethically all-important feature of the case is that the real-time brain snapshots are compared with previous readings that were made of that same shopper. Don't forget that this is a case in which no disclosure takes place, and so it is a case where this shopper's neuro-profile is being recorded, stored, manipulated, and compared, without his permission and quite possibly against his interests. This is, then, a prima facie breach of privacy (of both one's person and one's information). An important argument against neuromarketing, then, is this: at its worst it will further erode an ethical boundary between self and world at a point that was formerly thought inviolable: the skin (Fischbach and Mindes 2011, p. 361). Suppose some shopper, standing quite still, and with a deadpan facial expression, views a pale blue dress. From her behavior, then, there are no real grounds to infer her thoughts. The scanner, meanwhile, revealing high activity in the orbitofrontal cortex, anterior temporal pole, and amygdala, tells a story about visual memory and emotion. This pale blue dress has evoked an emotional response in the shopper, likely involving a memory of some past episode.

Now there are several difficulties with what has just been described. First, the degree of specificity that attaches to snapshots at that level of description – "visual memory," "emotion" – is far too general to generate meaningful assumptions about

what, *exactly*, this person is thinking. That is problematic for a marketer working out how to capitalize on such impoverished information, and it is, insofar as that is true, thereby a less worrisome state of affairs for the ethical evaluation. Intuitively, do you object more to the fact that another has determined your emotional state from secretly scanning your brain or to (say) knowledge that some shop assistant, who knows you as a regular, was peering at your sad face? There does not seem to be a great deal of difference. But, some may, intuitively, disagree.

So, let's consider some data. In a 1997 study (Nwahukwu et al. 1997), an examination was made of people's evaluations of advertising strategies. The significant determinants were given as consumer sovereignty and autonomy and the harmfulness of a product. On the question of autonomy, emphasis was on the ability one has to recognize and neutralize the manipulations that are taking place. Yet, just as no manipulation is taking place while someone secretly peers at my sad face, no manipulation takes place as the scanner snaps my glowing amygdala. No manipulation means there is nothing to neutralize. Now one might respond here that given a certain level of brain-scanning accuracy, there is, at least, *potential* manipulation, say in the case where the machine provides much more detail, and a person in a monitoring booth retrieves this detail and passes it on to a salesperson who then says "bring back memories does it?" Suppose the targeted shopper asked the sales assistant "yes, reminiscing. . .how did you guess?" and was told "you just looked lost in the past" or some such thing. This kind of deceit would naturally send a shiver up many a Kantian spine. And those less exercised by the deceitfulness of the manipulation would perhaps also worry that in lowering the standards of transparency, the stability of the institution of market transactions might take the first slip down a worrisome slope.

Novel Ethical Problems?

Take a step back. This example is fictitious and designed to explore an ethical implication. In particular the unlikely presupposition was put in place that scanning takes place secretly. Nevertheless the case is instructive because – based on a principle of proportionality – the degree to which the practice is ethically dubious can be seen, roughly, to track the successfulness of the manipulation. Now, is it worrying that surreptitious scanning of brains will enable manipulation of customers? This question has two interpretations. One is that scanning raises an ethical difficulty that is novel. The other is that it exacerbates (perhaps significantly) an existing ethical dimension to the marketing practice. There are good reasons to think that neuroscanning does not raise a novel ethical challenge and that the degree of exacerbation depends entirely on the type and degree of success of the scans, as just discussed.

Neuromarketers are attempting to get access to information about the situated cognitive profile of consumers in order to understand the conditions that best motivate purchasing behavior. How new is this? Marketers have been attempting this *kind* of thing for a very long time indeed. Evidence of advertising, in one form or another, suggests the practice may have existed in ancient Egypt, Greece, and

Rome, and perhaps even earlier (Bhatia 2000). Modern advertising techniques are dated from the late 1800s. The most modern techniques in which members of the academy (usually those from the social and psychological sciences) join with marketers to inform them about what motivates the consumer go back quite a stretch to a period immediately after the Second World War. The remarkable book by Vance Packard called "The Hidden Persuaders," from 1957, discusses in great detail a range of practices occurring even then. It describes a "depth approach" to marketing in which insights about the subconscious nature of purchasing decisions are gleaned. In the depth approach it was recognized that many buying decisions are generated by processes that bypass the rational self. Insofar as that is true, campaigns were designed to cause purchasing behavior in whatever way worked, rather than cause purchasing behavior via the conscious reasoning mind. Thus, the real reason for deployment of a persuasive technique was worked out in advance by scheming marketers (p. 31). Packard continues:

> Certain of the probers. . .are systematically feeling out our hidden weaknesses and frailties in the hope that they can more efficiently influence our behaviour. . .[some are] probing sample humans in an attempt to find how to identify, and beam messages to, people of high anxiety, body consciousness, hostility, passiveness, and so on. A Chicago advertising agency has been studying the housewife's menstrual cycle and its psychological concomitants in order to find the appeals that will be more effective in selling her certain products. . . The same Chicago Ad agency has used psychiatric probing techniques on little girls. Public-relations experts are advising churchmen how they can become more effective manipulators of their congregations. In some cases these persuaders even choose our friends for us. . . (pp. 32–33)

For those who imagined that the alliance between marketers and some members of the academy was a relatively modern incarnation dating back only two decades or so, Packard's account may come as quite a surprise. He painstakingly details the practices of an already highly sophisticated and institutionalized approach to developing ways of bypassing the consumer's conscious awareness of what is taking place within a commercial transaction. Suffice to say, neuromarketing is simply an expected recruitment of an available technology that widens an already impressive suite of existing techniques for hidden persuasion. The aim is the same. The means is new. It might be thought, then, that the only question to ask, of ethical relevance, is one about how successfully neuromarketing fulfills the ever-present aim of probing the vulnerable consumer. That is a key question, no doubt, but as mentioned, another important area raised is brain privacy. There is good reason to think that worries about brain privacy are, to a large extent, overblown.

In the present context, some morally dubious advertising practices include those that lead to boundary crossings, targeting of consumers, and nondisclosure (Kennett and Matthews 2008). What exactly are these, and what is their relevance to neuromarketing? Advertising messages may be restricted to conventional spaces such as billboards or breaks between television programs, or they may intrude into noncommercial areas, as happens when product references are inserted into movies, novels, or creative works. People objecting to the latter are worried about boundary crossings. Undisclosed advertising examples include ads disguised as public

announcements; or comment, but paid for by a company; social actors (people in bars, perhaps even friends) secretly buzzing product; or subliminal messaging. Targeting occurs when an audience is selected because their profile makes them more likely to be receptive to the message. Companies know that advertising is less cost-effective when more of the targets ignore the message which occurs in mass campaigns. Most advertising campaigns have a degree of targeting – TV ads for toys don't run at midnight – and that's plain good sense. It is targeting of the vulnerable that is problematic. In the ethical evaluation of neuroadvertising, it is important to focus on questions of brain privacy where boundary crossing, targeting, and nondisclosure all feature.

Paradigm Cases

In neuromarketing (more broadly now), the focus widens to consider such things as product and service design, distribution, and pricing and their impact on consumer evaluations of risk and reward, their choice making, and the mind-brain processes leading to purchase decisions. Another question is whether scanning could be applied to other stakeholders in a market, for instance, employees. It should be noted that if scanning is regarded as a form of lie detection, legal hurdles will prevent this. In the USA, for instance, the Federal Employee Polygraph Protection Act 1988 prohibits employers from requiring or suggesting such a test be taken. And Murphy and Greely (2011, p. 650) discuss a recent district court ruling in the USA (United States v. Semrau 2010) that excluded fMRI-based lie detection material because of a failure to meet the standards of admission of scientifically based evidence set down federally.

A study in 2004 is regarded almost as archetypal in the field of neuromarketing. Researchers observed preferences for one brand of soft drink over another, where (in condition 2) the only relevant variable was brand knowledge of one of the samples, and where previously (in condition 1) this variable was absent. In condition 2, subjects displayed a statistically significant preference for the known-brand samples. In condition 1, fMRI imaging revealed consistent activation of the ventromedial prefrontal cortex (an area associated with decision-making and risk assessment), but in the brand-cued condition, in addition to the VFC, other areas of the brain were recruited – the hippocampus (involving processing of, inter alia, episodic memory information), dorsolateral prefrontal cortex (associated with, inter alia, affectively laden social judgments), and midbrain (associated with, inter alia, habits and motivation). The researchers suggested that two systems operate in concert to potentially bias decisions based on cultural meanings. When a brand is rich in such meanings, its associations work their way into memory content. These are affect-laden information pathways which have the potential to bias preference judgments, said the researchers (p. 385), and it is known that the recruited brain areas are implicated in cognitive functions of this type (McClure et al. 2004). The study is regarded as significant because it provided hard evidence – *brain* evidence! – that a particular kind of advertising that establishes a certain kind of

brand reputation is internalized and processed by the consumer in decision-making over product. So, it provided marketers with reassurance that the billions spent on brand promotion and loyalty campaigns was not only money not wasted but indeed important territory to battle it out for the competitive edge.

Neuroscience is thought to be able to help in other areas of the market, for example, in pricing policy. In lay terms the negative price effect refers to the tendency for demand of a good to reduce as its price increases, and the positive price effect refers to an increased demand. The psychology of this seems straightforward: on the one hand higher prices represent a net loss, and demand reduces; on the other hand higher prices signal higher quality and prestige offsetting loss perception and a rise in demand. These effects are, therefore, category sensitive and dependent on consumer knowledge of the market. So, for instance, positive price effects often obtain for luxury consumables such as wine or cars. Negative price effects obtain most clearly for familiar everyday substitutable items of known and stable quality, like a range of foodstuffs, such as milk, eggs, or biscuits. Since it is not always clear which effect will obtain in the pricing of certain types of goods, marketers are keen to have the best neuro-motivational analysis of potential consumers in order to get their pricing approach set to maximize profits.

A well-known study in this connection comes from Plassmann et al. (2008), who were interested in the neural correlates of the positive price effect. (See Knutson et al. (2007) for an fMRI study of the negative price effect). In brief, subjects' appraisal of wine quality was sensitive to price as the positive price effect might predict. Taste sensation experiences, unlike the uninterpreted raw feel itself, are complex. For taste sensation experiences, there are three separable neural systems: what takes place at the cellular level of taste buds, the neural pathways that carry the elicited transmitter, and those primary brain regions into which these transmitters project, namely, the brain stem, limbic areas, and some higher cortical regions. In the Plassmann study subjects who experienced the expensive wines as being of higher quality displayed cortical recruitment in their fMRI scans.

An Unstable Situation

Neuromarketers find these kinds of results to be of enormous interest because they seem to show evidence that market evaluations are modulated by brain regions thought responsible for higher cognitive function. More specifically, these results confirm, for marketers, that buying decisions can be biased by cognitive processes that have little to do with the internal composition of the goods themselves (given that a certain threshold of quality is achieved) and a lot to do with exogenous features of the purchasing event.

A number of pragmatic questions are here raised. For instance, why is it that evidence from neuroscience is deemed especially useful and reliable for application in marketing practice? Why are marketers so focused on an internal feature of commerce, the consumer brain? And why do they think this information is actually and potentially useful?

Neuroscience explanations are alluring. Perhaps they are because of the hope of mind reading – a capacity science (allegedly) might have to identify and describe a person's thoughts, in particular her beliefs and desires. Another reason might be that our brains don't lie. Agents may not really know why they act, and they may not always have the capacity to explain why they acted, and that is because in various contexts the potentially dissociable subpersonal mechanisms implicated in behavior are revealed for just that, and the connection between (articulable) reasons and actions is lost. For instance, a study by North et al. (1999), showed that participants' buying decisions – between bottles of German and French wines that were otherwise the same – were significantly affected by background (German or French) music, yet only one of the forty-four participants said so, and 86 % explicitly denied that music had anything to do with their choice. So, although agents sometimes cannot nominate the real causes of their actions, neuromarketers continue to be dazzled by the apparent fact that big machines can. This continues to be an enormous attraction, but there is reason to be suspicious.

The attractiveness of neuroscience in the market can be measured. Typing "neuromarketing" into Amazon Books yielded 219 hits (2/11/13). These are, in general, not reprints, and nearly all have publication dates from around 2009. It doesn't take long to find examples of hype, especially online. Consider this gem from CNNMoney: "And neuromarketing scans are very good at pinpointing exact points of reaction. Pradeep cited a study for an unnamed company that makes chips and salsa. They found that the moment a snacker lifts a salsa-covered chip to his mouth, before taking a bite, 'that moment is extremely evocative for the brain. Your brain just goes nuts.'" In 2000 there were no peer-reviewed articles, no Google hits, and no neuromarketing companies. In 2004 there were 5,000 Google hits, climbing almost vertically up the y-axis. In 2010 there were 250 published articles and 150 neuromarketing companies (Plassmann et al. 2012). The suspicions about the overvaluation of neuroscience explanations can be investigated as well. A paper by Weisberg et al. in 2008 showed that students and nonexperts tended to find flawed neuroscience explanations of psychological phenomena more satisfying than explanations lacking these flaws.

Summing up, this is an unstable situation: neuromarketing is nascent, growing exponentially, and, by the marketers, seemingly highly trusted. However, many think there is a reason to hesitate and reflect on what neuroscience can really do here; others are outright skeptical, and others think there is something fundamentally ethically misplaced about applying neuroscience in a commercial context. For example, Fischbach and Mindes (2011, p. 361) write that neuromarketing "is troubling" because it involves "distortion and potentially inappropriate commercialisation of science." On the question of skepticism, most of the focus is not on the accuracy, or design, of the science itself, but rather the estimation of the value of the information it provides for the market. And here, the thought is that, just like Weisberg's subjects, market nonexperts' bedazzlement is preventing clear thinking about what neuroscience is able to deliver *in principle*. Paul Wolpe (Director of the Emory Centre for Ethics), for instance, has commented in a New York Times interview that neuromarketing is really only a kind of "pop" neurology for product

positioning, and it will not get people to buy or buy more. One also gets the feeling that much of the overblown confidence about neuromarketing's possibilities issues from the market and the more restrained estimations issue from the laboratory – a kind of institutionalized version of both the endowment effect and the Dunning–Kruger effect working together. On the endowment effect (roughly, where people overvalue what they own), it seems likely that neuromarketing companies' financial and psychological investment in the practice bolsters their willingness to accept its results. On the Dunning–Kruger effect, according to it, poor performers in particular grossly overestimate their abilities and intellect precisely because their incompetence deprives them of the acumen needed to identify their own weaknesses (Ehrlinger et al. 2008).

Still, to be fair, taking seriously the nascent state of the science is important, and even claims about "in principle," possibilities have to be made from behind a firewall of ignorance. Compare the failures in the early days of computing to appreciate Moore's Law in relation to the biannual doubling of integrated circuits (Moore 1965). Moreover, consider the limitations of mechanical emulations of computing functions relative to electrically based switching components, the latter allowing novel functionality based not on a principled distinction between one kind of computing and another, but a simple difference in concrete realizability. So, there are lessons here for the overly pessimistic as well.

In addition, drawing on an earlier distinction between persuading the consumer and understanding what motivates the consumer is instructive. To argue skeptically that neuromarketers will never locate the so-called buy button constitutes a straw man argument when neuromarketers are attempting no such thing in the first instance. And many neuromarketers are keen to emphasize just this important distinction. According to two neuromarketing consultants,

> The use of brain-imaging will never enable marketing professionals to discover that Holy Grail of market research, a 'buy button' – some mythical region of the brain which need only be stimulated to compel consumers to purchase a product whether or not they actually want to do so! It will never be found because, of course, it does not exist! More realistically, we believe, Neuromarketing offers the prospect of gaining a better understanding of how the brain responds in a wide variety of everyday situations. In addition to proving of great commercial value such research offers the possibility of increasing our knowledge of brain function among a non-clinical population as it extends powerful medical technologies into a new and challenging area of research.

The quote is from David Lewis and Darren Bridger (2005, p. 37), who seem careful in their assessments of the limits of neuromarketing, though at the end that circumspection seems to dissolve into a flourish designed to bolster confidence in what they claim neuromarketing can achieve.

Skepticism

One worry that has been expressed is that neuromarketing doesn't tell us much we didn't already know or at least strongly suspect on independent grounds (see, e.g., Levy 2009, p. 11). Erk et al. (2002) used fMRI to study the brain activation patterns

of 12 male subjects who viewed photos of different classes of cars, then rated them for attractiveness. They had hypothesized that sports cars are associated with wealth and social dominance, and since dopaminergic reward circuitry is implicated in social relations like dominance and social status, they said, it would not be surprising if brain correlates were found associating sports car viewing with the relevant circuitry. This is indeed what they found. In particular they found that the level of perceived attractiveness of a car was correlated with the level of activation in the ventral striatum, a key brain site from which dopamine projections move into other regions implicated in motivation. These findings are important, so it is said, because of an inference linking product design to reward to purchasing behavior. Unfortunately, this is an expensive way to find out something discoverable by asking a car dealer. Less facetiously, Erk's hypothesis could be tested by social psychologists collecting the relevant data on purchasing patterns, earning capacity, and psychological profiling.

Now this is not to say that there is *no* reason for engaging in studies of the kind Erk et al. performed, in case they are viewed legitimately as baby steps for more sophisticated ones later. Paradigms in normal science take time to build and develop, and so many early studies serve as foundations for them and for further work incorporating these earlier accomplishments.

Levy (2009) raises a novel objection to the uses of neuromarketing. Stepping back, ask first: what is at the core of the ethical objections to marketing practices? The answer is that they are objectionable when they bypass autonomous decision-making in the marketplace. If agents are manipulated into buying a product, they have not consented to it. If that is at the core, and surely it is, then the ethical test for market practices at the buyer-seller interface is whether manipulation is present. Levy says that insofar as we are overly focused on the internal interventions of neuromarketers, we risk overlooking the most powerful manipulative techniques marketers deploy in the *external* environment.

There is a type of consequentialist principle operating here, namely, to pay close attention to the weakest empirical point at which there may be ethical breaches. If one's attention fastens on to the potential for neuro-manipulations, one may well lose sight of those weaker external points. Arguments in applied ethics must identify the relevant moral principle, and they must determine the empirical conditions in which it is likely to be compromised; less obviously, arguers must remain sensitive to an epistemic bias concerning the most likely source of their ethical concerns. In the present context a sensible policy to deal with the last point would be that observance of the distinction between agent and environment makes trouble when evaluating the ethics of neuromarketing. Levy goes on to make a connection between Baumeister's ego depletion hypothesis (1998) – willpower is a kind of exhaustible resource – and manipulations in the shopping environment that, albeit implicitly, exploit the vulnerable consumer. This thesis has also been connected with self-regulation and impulse buying (Vohs and Faber 2003).

In this connection it is somewhat surprising that little, perhaps no, explicit link is made in the literature between addiction neuroscience and neuromarketing. This is particularly so when one considers the legal availability of addictive products such

as alcohol. One might have thought that neuromarketers would be interested in the neuropsychology of consumers who develop a habit, one in which consuming the product of choice occurs as a kind of ritualized sequence or action repertoire. They might be tremendously interested in the state of a brain that results from that kind of life. David Nutt (2012, p. 136) has recently suggested an elegant model in addiction neuroscience in which pull factors, higher-than-expected pleasurable reward (dopamine), reduced suffering (endorphins), memories (GABA/Glutamate), and meanings (serotonin), combine with push factors, impulses (noradrenaline), compulsions, and withdrawal (multiple neurotransmitters), which then all feed into a state of wanting. The identification of the addicted brain is the identification – by many marketing standards – of the ideal consumer. Notwithstanding the legality of the products neuromarketers are concerned with, researching the neurological conditions of addiction for a commercial outcome is presumably not seen as ethically defensible. This would seem, on the other hand, to represent what has been called a dual use dilemma for addiction neuroscience. But that thought cannot be pursued here (see Miller and Selgelid 2009).

Are There Grounds for Moral Disquiet?

Bringing together the threads of the discussion, so far, there are indeed grounds for *some* disquiet in regard to the future of neuromarketing. What might be potentially morally problematic here? Assume, first, surely not implausibly, that neuromarketers, *qua* marketers, are designing a model to maximize the market share obtainable by business X, where the consumer (including his brain) and aspects of the consumer environment are conceptualized as parts internal to the same system. Then, they are not really interested in agents separate from the shopping environment; they are interested in oiling the components of the system to optimize the profits of X. So, they will be interested in the work of Baumeister, and they will be interested in the work on subliminal brand priming (Murawski et al. 2012; Winkielman et al. 2005), work done on the effects of the hormone oxytocin on trust (Zak et al. 2004, 2005), and any other work that might facilitate the movement of a product or service in an exchange setting. They will of course be especially interested in experiments that utilize brain scans, for example, as a way of confirming the effectiveness of certain communication strategies. (As did Ambler and Burne (1999) and Ambler et al. (2000) when testing the relevant role of cognitive versus affective strategies in brand advertisements by administering beta-blocker drugs to participants (which dampen affective responses) to show that in the normal case emotionally charged advertisements are more effective in generating memories of the brand.) This makes plausible the view that neuromarketers (*qua* marketers) are interested in brains-in-the-market; the brain, hitherto inaccessible to market producers and advertisers, now takes its rightful place in the model to complete the picture.

Assume also the distinction between brain types and tokens. When McClure et al. did their research, they sampled many individuals because they were

interested in truths about what the human brain does *in general*, in response to like-stimuli. The thought here is that such general truths carry more robust predictive value and so more value to the marketer looking for efficient advertising strategies. That is correct enough, but the level of generality here is insufficient to properly and effectively target the individual customer. Even the environmental manipulations have their limitations. Absent specific historical information about particular consumers who present within a store, a store that has maximized the product-moving effectiveness of its design (e.g., in the placement of its products), will nevertheless reach saturation level with respect to the possibility of further sales. If the store had access to information about particular regular customers – their brain scans and buying patterns, all crossmatched – more targeted and effective marketing strategies could no doubt be achieved. If the earlier scenario involving real-time mobile scanners were in place, it seems not unlikely that, for instance, a shopper's emotional response could be discerned with reasonable accuracy, which might be seen as useful information for a shop assistant. This would be brain level, token-specific, historically accurate, up-to-date data that delivers a profile of the consumer. Such information may be kept on a database, triggered in real time via face-recognition software, and delivered at the right moment and setting to calculate the best sales approach given the current state of the consumer.

That description seems to pinpoint the empirical conditions that most worry those who are concerned about a consumer's right to control his or her privacy, both informational and so-called perceptual privacy (Matthews 2008, p. 130). However, this worry can be downplayed by analyzing away the grounds of the fears by (1) talking about what is really at stake in questions of privacy, (2) thinking about what "mind" refers to in "mindreading," and (3) noting again the inherent deficiencies of brain imaging for the alleged neuromarketing purposes. Should this attempted debunking allay the worries of Fischbach and Mindes (2011, p. 361) and others that neuromarketing could lead to an "invasion of brain privacy"? No, not completely. It is important to sound a note of caution about the possibility that companies will gain control of neuromarketed personal records built up over a period of time, leading to aggregated datasets of quite detailed information. In this form it may be stored for use, distributed, traded, sold, and as sometimes happens misused, accidentally leaked, and so on.

(Questions of brain privacy also arise in neurolaw, and sometimes there is a reversal from protection of brain information to attempts at having the contents of one's brain utilized for, in some cases, legal exoneration. In Harrington vs Iowa, testimony making use of "brain fingerprinting" was introduced in an attempt to exonerate a convicted murderer. Lawyers making use of the so-called P300 effect attempted to show, through evidence given by Dr Lawrence Farwell, that the defendant did not have knowledge of the murder. The P300 effect involves the emission of a signature EEG-recognizable pattern (coming 300 milliseconds poststimulus), and (controversially) it is claimed to reveal information stored in a subject's brain (see Peters 2005).

Skepticism Again

First, consider (2) and (3) above, taken together. The literature in relation to the accuracy and usefulness of brain imaging data varies. In Canli (2006), neuroimaging, he claims, predicts some behavior with more accuracy than self-report. Others, such as Gazzaniga (2006, Chap. 7) and Levy (2007, Chap. 4) are not so confident. The question of accuracy is partly open and partly a conceptual matter. On the empirical openness point, the accuracy obviously depends on technological improvements as discussed above. However, consider a known feature of fMRI that would seem an impediment to neuromarketing utility. They deliver relatively high-value spatial resolution scans, though getting the correct sample frequency (temporal resolution) is problematic given that blood takes a relatively long time to redistribute within the brain, and so this "hemodynamic lag" negatively impacts the capacity to make accurate brain-mind correspondences where the possession of temporal synchrony is salient. Moreover, since their predictive error is a function of the signal change between two conditions, the sample size within an experiment is technologically critical to the statistical power assigned to the result, though it depends on the relevant cognitive task (for the technical details of all this, see Desmond and Glover 2002). Suffice to say, these observations suggest a limitation for fMRI-type scanning as a means to identify "one-off" buying situations involving single individuals operating in novel conditions. (And all of this is not to even mention that they are car-sized, non-portable, dangerous, and immensely expensive machines (between one and three million dollars)). There are other difficulties regarding the limitations of fMRI, including extrapolation of correlates to different population types, different circumstances, and sampling biases arising from an inability to compare published results with unpublished null results from similar experiments (see Farah et al. 2008).

On the conceptual question, what is supposedly being read when our shopper enters the store? A useful first distinction here is that between dispositions and states. The store brain scanner might detect activation in posterior regions of the hypothalamus, accurately indicating a state of thirst, and that *could* be useful information. But the scanner won't be so good at predicting a range of specific behaviors based on descriptions of static states, even very detailed ones, of my brain anatomy. In other words it won't be very good at identifying how I am *disposed* to act. This is partly to do with the fact that it would not take into account the range of environmental triggers of such dispositions but also because there are too many possibilities. One way of unpacking the notion of a disposition (for present purposes anyway) is in terms of a set of counterfactual propositions true of some agent. The question, then, might be whether the scanner (in contrast with cheaper garden variety methods involving say talking to people) could generate data for deciding on the truth of these:

Were this shopper to X, he would Y
Were this shopper to be X'd, he would Y

And so on. On the question of states, even here there are difficulties. If, for instance, moods are regarded as internally generated background affective states, which, of conceptual necessity, last longer than certain emotions, then it is doubtful

scanners will accurately reveal mood types in normal subjects. And it would seem impossible to identify the intensity of a mood relative to what is normal for that individual. The scanner will be better at identifying certain kinds of emotion – for example, disgust, enthusiasm, fear, and so on – because these affective states are short-lived, action-oriented, connected to distinct facial expressions, and typically dependent on real-time environmental responses. However, in that case, they are typically public expressions, and so by their very nature privacy is relinquished with respect to them.

What about states in which my thoughts have linguistic content? This appears to be the gold standard for mind reading. Of course nothing of the sort is, at this point, on the technical horizon, and even were it to be, legal impossibilities would bar general deployment of such a powerful machine. Still, it is nevertheless a useful exercise to consider what is ethically at stake in such a possibility. Would marketers be tempted to use a machine that secretly revealed what a shopper was thinking, in all its detail? Probably, but they would do so at their own peril. To show why consider work done by Thomas Nagel who explored what might happen in case, we lost all reticence.

> A and B meet at a cocktail party; A has recently published an unfavorable review of B's latest book, but neither of them alludes to this fact, and they speak, perhaps a bit stiffly, about real estate, their recent travels, or some political development that interests them both. Consider the alternative:
>
> B: You son of a bitch, I bet you didn't even read my book, you're too dimwitted to understand it even if you had read it, and besides you're clearly out to get me, dripping with envy and spite. If you weren't so overweight I'd throw you out the window.
>
> A: You conceited fraud, I handled you with kid gloves in that review; if I'd said what I really thought it would have been unprintable; the book made me want to throw up – and it's by far your best. (Nagel 1998, p. 12).

The analogical significance of this example to neuromarketing is not immediately obvious until one connects the failure of social civility to the potential failure of market communication. Perhaps Nagel overplays things a bit, but the general philosophical point is that privacy provides protective armor for the conventions of civil life. Removing that armor leads not just to disruptive losses in social communication such as this one, but more serious losses to a range of liberal conventions that permit social life to proceed and flourish.

Applying a version of Nagel's take on this in the face-to-face market context presents a dilemma. Suppose the salesperson knows what the consumer is thinking. Then either the consumer knows this or not. In the case where the consumer knows that the salesperson knows what he is thinking, conversational interactions would be unstable, strange, and unpredictable in content. As a communication strategy, this short circuiting of the norms governing selling behavior seems counterproductive to say the least. On the other horn of the dilemma, the consumer does not know that the salesperson is able to determine exactly what he is thinking in real time. On this horn, a flagrant breach of privacy occurs, a kind of voyeurism motivated by a commercial imperative. In other words, the admittedly (currently, and perhaps even in principle) technically impossible gold standard for mind reading at the store

is either self-defeating or grossly and unarguably unethical, and no properly morally informed and motivated jurisdiction is going to provide statutory permissions to such an institution.

Privacy

Consider now (1) above, namely, what is really at stake in questions of privacy. The definition of privacy is contestable and not just because it is contested, but because two of the salient conditions of privacy – separateness from others (of person, and of personal information) and control over the public-personal boundary – are apparently at odds. The problem is that the use of "privacy," and cognate expressions, carries with it the meaning of both conditions, but logically, one condition may be satisfied and not the other. For instance, a person might voluntarily give up all privacy. In this situation there is no separation from others (and seemingly no privacy), yet full control (and so seemingly privacy is exercised). On the other hand, a neglected elderly person might remain free from intrusion (a condition of privacy), when being left in such an isolated condition is indicative of his loss of control over his interaction with others, his control over the private-public boundary. Resolving this tension is no easy matter, but perhaps it should be said, for present purposes, that privacy is personal isolation, of a certain kind: the kind that occurs when an individual chooses her isolation relatively unconstrained. If this is right, in a privacy violation one objects to another person (or institution) actively perceiving his person (or information), and by that means subjugating him to a motive of theirs that he cannot share (Matthews 2008).

The seriousness of a breach of privacy usually depends on the potential for harm. In the US state of Ohio, Beverly Dennis, a 57-year-old who lived alone, received a letter from a stranger who detailed extensive personal knowledge about her. The letter writer then outlined a range of explicit sexual fantasies he had about Dennis in relation to her preferred brand of hand lotion. It turned out the letter writer was Hal Parfait, a Texas prisoner who had been convicted for invading another woman's home, threatening her children and raping her. Parfait had accessed the personal details of Dennis because Metromail, a data collection agency, had subcontracted the task of inputting personal data – Dennis had earlier completed a discounts coupon – to the Texas Department of Corrections.

The important question for brain privacy, then, is this: what (special) harm may come when neuromarketers obtain my brain information in the non-consenting case? In answering this question, let's assume they have a mind reading device that cannot interpret my linguistic stream of consciousness and cannot determine my background mood. But it can, let's say, tell, in real time, when I am indecisive because of price; it can pick with a 20 % error certain specific emotions; it can sense my loyalty to certain brands (or types of brands), and so on. It can, then, apparently, provide limited help to sales staff in framing their pitch to me.

Our analysis of privacy helps here. As a consumer I have tacitly consented to a situation in which the seller is trying to sell me something I want or to convince

me that I want something (even if perhaps I don't *really* want it). In that case it is just false that the neuromarketer is subjugating me to a motive of theirs I cannot share. My motive in that context is up for grabs. Ceteris paribus, I am not likely to be harmed by the fact that the scanner has delivered information to the salesperson that may make the difference between my buying and not buying. It is not as though the scanner can read my mind and find out my address. (The Dennis case above is in a different league.) In terms of viewing my person, what we object to in perceptual privacy (think here of cases of voyeurism) is that another person has impermissibly viewed my body. The privacy-relevant object here is my self-presentation, which in this context is essentially a presentation of who I am, at the surface. In the case where someone became voyeuristically motivated to view my brain scans, my resentful response that this violated my privacy seems entirely misplaced.

A final point about privacy does express a residual worry. It is one thing to scan the brain of a customer on one occasion, quite a different matter to repeatedly scan the same person's brain over a period of time, thereby building up a *bank* of data. Helen Nissenbaum (1998) provides the locus classicus for the worry being expressed here. Observances of digitally enabled capacities for incrementally obtained information lead to losses of privacy over time, or what she calls the problem of privacy in public. She writes:

> I have in mind here, the principle of contextual integrity and the principle that no information is genuinely "up for grabs", available for purposes such as aggregation, profiling, and data mining. These principles offer criteria for discriminating from among the various forms of public surveillance and record-keeping those that constitute moral violations of privacy and those that do not. (p. 596).

The potential threats to privacy represented by neuromarketers who hold brain information are in this sense no different from any other kind of threat to private information. As such, one should not downplay the threat and nor should one imagine that issues of brain privacy are sui generis. The right response, then, is to assimilate these concerns to the ordinary ethical concerns we have in other sensitive areas. For instance, neuromarketers should be subject to privacy protocols just as medical practitioners are.

Conclusion

The arguments here lead to a mildly skeptical approach to the claims of neuromarketers regarding their capacity for generating valuable data for commercial decision-making. What has been claimed is that to the extent that neuromarketers do succeed in their endeavors, a commensurate ethical concern is raised mainly in relation to questions of privacy, and that is because what is found most offensive in this context is the aggregation of personal data and a loss of control over what may be done with it. These legitimate worries give rise to the need to monitor those neuromarketing practices which risk this loss of control. But theoretically these are not special worries raised by neuromarketing.

Ethics of Implicit Persuasion in Pharmaceutical Advertising

104

Contents

Abstract

Direct to Consumer Advertising of Prescription Pharmaceuticals (DTCA) is a controversial practice permitted only in the United States and New Zealand. Central to why all other nations ban DTCA is concern about its capacity to impart complete, balanced, and accurate information that guides effective consumer decisions. Yet the debate has, thus far, paid scant attention to how implicit or unconscious persuasion in DTCA might influence consumer attitudes toward advertised drugs. In this chapter, one means of implicit persuasion, evaluative conditioning, is argued to have deleterious effects on the autonomous agency

that DTCA viewers bring to medicine choices and on the wider doctor-patient relationship. These effects suggest implicit persuasion should be given much greater consideration in the development of public policy on the marketing of pharmaceuticals.

Introduction

Direct to Consumer Advertising of Prescription Pharmaceuticals (DTCA) is legal in only two nations, the United States and New Zealand. Two primary concerns underpin the decision of all other countries to outlaw the practice. First, prescription drugs have significant potential to cause harm. Prescription status – a requirement that a doctor authorize and oversee use of a drug – is predicated on, among others, a need to safeguard against drug side effects and toxicity (Brass 2001). Prescription status implies, therefore, that the drug carries heightened risk compared to, for example, medications that can be sold over the counter at a pharmacy.

The second concern is that any (legal) decision to take a prescription medicine occurs within the confines of the doctor-patient relationship. That relationship is governed by well-established ethical and legal principles. Prominent among them is a duty to respect and promote patient autonomy, that is, self-governance. That duty demands patients give free and informed consent to medical treatment, including prescription medicines. Respect for autonomy stresses the integrity of the information that patients rely on to make medical decisions. It is known that exposure to DTCA influences patients' requests for drugs and, as a result, doctors' prescribing behavior (Mintzes et al. 2003). Hence, the quality of product information provided by DTCA can wield formidable influence on the doctor-patient relationship.

Opponents argue that DTCA harms by promoting excessive and sometimes inappropriate pharmaceutical use (Hasman and Holm 2006). In support, there is substantial evidence for the persuasive force of DTCA. On one estimate DTCA returns around $US4 for every dollar spent by pharmaceutical manufacturers (Mintzes 2009). Further evidence suggests that increased sales of advertised medicines are driven by patient requests. People who view DTCA are more than twice as likely to make brand-specific drug requests compared to those in jurisdictions without DTCA (Mintzes et al. 2003). Doctors honor those requests in over 50 % of cases (Kravitz et al. 2005). Yet there is doubt whether improved public health results. Kravitz et al. (2005), for example, showed that patient requests for a brand-specific drug were met in 55 % of instances where the drug was not a recommended treatment, specifically, antidepressants for adjustment disorder. And in a meta-analysis, Gilbody et al. (2005) concluded that while DTCA increased drug prescriptions, no study showed evidence of overall public health benefit.

Opponents further argue that the persuasive intent of DTCA leaves informational integrity as a secondary concern. Advertisers are, on this view, motivated to provide inadequate, incomplete, imbalanced, or misleading drug information if, in so doing, the drug is presented in a more favorable light (Hasman and Holm 2006). This concern is heightened in the United States by the absence of any requirement

for regulators to vet DTCA pre-release. Rather, ads are subject to post hoc scrutiny only if a complaint is made (Food and Drug Administration 2012). The result, opponents argue, is an impoverished understanding among DTCA viewers that militates against autonomous choices and informed consent.

DTCA proponents typically counter that advertising is an important means of promoting awareness of both diseases and their treatment (Hasman and Holm 2006). This is held to be of special significance for the socioeconomically disadvantaged for whom advertising, especially of the broadcast variety, is a primary source of medical information. It is also argued that DTCA acts as a reminder function that enhances compliance of existing patients with their medication regime (Mintzes 2006). Proponents further argue that DTCA bans are an unjustified constraint upon free speech. These grounds formed the basis for legal action challenging the constitutional validity of Canada's prohibition of DTCA (Priest 2007). That process was terminated, however, before any judicial decision was reached.

Yet, to date, the debate has largely ignored consumer psychology research that increasingly shows how advertising persuades outside of awareness. These subtle forms of persuasion may impact the attitudes viewers come to hold about advertised drugs, while escaping current regulation. Further discussion of unconscious or "implicit" persuasion requires some clarification of terms. There are three prominent accounts of implicit persuasion (Chartrand 2005). First, the individual may be unaware of the persuasive stimulus. In subliminal advertising, for example, frames in a commercial are presented too briefly to be consciously processed. Second, the individual may be unaware of the process by which persuasion occurs. As will be detailed, this form of implicit persuasion can occur even when all stimuli are supraliminal, that is, above the threshold of consciousness. Finally, individuals may be unaware of the attitudes that they come to hold as a consequence of the persuasive process. This third possibility is predicated on a dual theory of attitudes (Wilson et al. 2000). On this view, people hold conscious or explicit attitudes that they can report, but also implicit or unconscious attitudes of which they are unaware. People may report, for example, explicit attitudes of racial impartiality yet be gauged, on measures such as the Implicit Association Test, to hold implicit attitudes consistent with racial prejudice (Greenwald et al. 1998).

The following discussion focuses on the second category; implicit persuasion where the individual is unaware of the persuasive process. Subliminal persuasion is not addressed because of uncertainty about its real world effectiveness (Vargas 2008) and because it is almost universally prohibited. Nor are implicit attitudes considered, primarily because of controversy over what implicit measures actually assess, and the degree to which they predict subsequent behavior (van Ravenzwaaij et al. 2011). The focus is, therefore, on persuasion using supraliminal stimuli where the resulting attitude can be reported by the individual, yet where the mode of persuasion remains hidden. The importance of this category is that it covers techniques that are permissible within current regulations and detectable on relatively uncontroversial measures.

A number of techniques fit this classification. For example, the mere exposure effect (Zajonc 1968) describes how repeated viewing of a neutral stimulus can

cause people to like the stimulus. Consistent with mere exposure, repeated viewing of advertised products increases both familiarity with and liking of those products (Fang et al. 2007). Priming describes how advertisements act as hedonically charged cues that enhance the product's mental accessibility and activate striving for them (Chartrand et al. 2008). Framing effects occur when identical information is presented in different ways, causing divergent attitudes to the target object. For example, the description "95 % fat-free" generates greater liking than does "5 % fat" (Kahneman et al. 2000).

Perhaps one of the best researched techniques in this category is evaluative conditioning, a variant of classical Pavlovian conditioning. Evaluative conditioning results from the pairing of a neutral stimulus, for which no special feelings are held, with a valenced stimulus, one that elicits either positive or negative feelings (Jones et al. 2010). With repeated pairing, the feelings and consonant attitude held toward the valenced stimulus pass to the neutral stimulus. In the case of a positive valence stimulus, the result is a positive attitude toward the previously neutral stimulus. In advertising, for example, images of happy smiling people may be used to condition positive attitudes toward a novel product, for example, a new brand of shampoo.

In the language of Pavlovian conditioning, the valenced image is termed the *unconditioned stimulus*, because it elicits positive feelings with no need for further manipulation. The neutral object, the shampoo, is the *conditioned stimulus* that takes on the positive valence of the unconditioned stimulus. The resulting positive attitude is the *conditioned response*.

In what follows, evaluative conditioning is used as a paradigm case of implicit persuasion in DTCA to examine the consequences for the autonomy with which consumers make choices about medicines, their capacity for agency in relation to those choices, and the subsequent impact on the doctor-patient relationship.

Empirical Evidence for Implicit Persuasion via Evaluative Conditioning in DTCA

In this section, evidence is summarized for the persuasive potency of evaluative conditioning, its operation in DTCA, and its implicit nature.

Evaluative conditioning has been demonstrated toward a range of conditioned stimuli including words (De Houwer et al. 1994), odors (Rozin et al. 1998), and human faces (Walther 2002), using various valenced unconditioned stimuli, among them, images (Pleyers et al. 2007), music (Eifert et al. 1988), and candy (Brunstrom and Higgs 2002). While concerns have been voiced that conditioning effects are difficult to replicate (Rozin et al. 1998), a recent meta-analysis of 214 evaluative conditioning studies concluded it to be a robust phenomenon (Hofmann et al. 2010).

In a typical study, Sweldens et al. (2010) used positive valence images to condition positive attitudes toward novel brands of Belgian beers. Smaller images of branded beer bottles were superimposed over a variety of larger positive images, including people water-skiing, sailing, and cuddling. Positive images were sourced from the International Affective Picture System (IAPS), a database where the

valence of each image has been systematically calibrated (Lang et al. 2008). Participants exposed to positive images reported more positive attitudes toward the beers than did those exposed to neutral valence images, for example, people reading a newspaper or napping on a subway.

While evaluative conditioning is strongly supported by research in social psychology, proof of its operation in DTCA faces some empirical hurdles. First, a "process pure" evaluative conditioning experiment involves repeatedly pairing a conditioned stimulus with unconditioned stimuli whose valence is known. Varying the valence of the unconditioned stimulus and noting consonant alterations in the induced attitude permit ascriptions of persuasive potency to the unconditioned stimulus. Yet, as De Houwer (2009) has noted, real world ads pair the product, the conditioned stimulus, with a variety of valenced stimuli including imagery and music, and also with propositional informational content. The multiplicity of attitude influences is an impediment to discerning the relative contribution of conditioning against other persuasive content.

Yet, as Biegler and Vargas (2013) have argued, there exist both conceptual and empirical rationales to accept the existence of evaluative conditioning in DTCA. First, imagery in DTCA relates closely to the positive valence pictures featured in the IAPS. For example, an ad for Lipitor (Pfizer 2010) features a man petting a dog and leaping from a jetty before swimming in a sparkling mountain lake. It is not coincidental that cute animals and majestic natural scenery figure prominently in the most positive valence images of the IAPS. There is also a database of sounds whose valences have been calibrated, the International Affective Digitized Sounds (IADS) (Bradley and Lang 2007). The most positive valence sounds include the music of Bach and Beethoven, people laughing, and a baby cooing. Uplifting music and the sounds of people enjoying themselves abound in pharmaceutical commercials. For example, an ad for the asthma inhaler Advair (GlaxoSmithKline) has children laughing after blowing bubbles and hitting a piñata at a sun-drenched outdoor party. Guitar music in a major key provides a soaring backdrop.

There is strong prima facie evidence for the existence of positive valence unconditioned stimuli in DTCA. Further, many commercials repeatedly present images of branded drug boxes and logos, which plausibly comprise the conditioned stimulus. The conclusion that evaluative conditioning will occur is compelling. Indeed, in an extensive review, Schachtman and colleagues concur that:

> [In] the case of paired events during advertisements, if the individual changes his or her behavior (attitude change, interest in purchasing the item) in the presence of the product or brand (the conditioned stimulus) as a function of pairings of this conditioned stimulus with an affective stimulus (the unconditioned stimulus), then this behavior can be said to be a conditioned response (Schachtman et al. 2011, pp. 481–482).

An experiment conducted by Smith et al. (1998) provides a supporting empirical rationale. On their construal, a commercial's positive valence elements, including imagery and sound, can combine to elicit positive affect. On this view, multiple stimuli of similar valence can comprise the unconditioned stimulus. Consistent with

this view, Smith et al. (1998) found commercials that elicited broadly positive affect also induced the most positive attitudes toward the featured product.

A remaining question is whether evaluative conditioning is applicable to pharmaceuticals. It might be argued, for example, that pharmaceuticals are not "neutral" stimuli and, therefore, may not be ideal conditioned stimuli. In fact, there is evidence that many connote drug treatments negatively (Benkert et al. 1997). If so, pharmaceuticals may evince differential susceptibility to conditioning compared to say, shampoo, or dishwashing liquid. Addressing this concern, Biegler and Vargas (in preparation) demonstrated positive evaluative conditioning toward a hypothetical influenza drug using valenced imagery from the IAPS. This study suggests that traditional conditioning techniques are indeed applicable to pharmaceuticals, albeit in relation to one category.

To sum, there is good evidence that evaluative conditioning is a robust effect that is operative in DTCA. But is its operation implicit, that is, outside awareness? To support this claim, it is necessary to look more closely at the conduct of evaluative conditioning experiments. A number of the studies cited earlier that successfully conditioned positive attitudes also included demand awareness checks (Brunstrom and Higgs 2002; Rozin et al. 1998; Walther 2002; Sweldens et al. 2010). These measures test to see if participants became aware of the investigators' hypothesis during the experiment. The danger is that awareness may cause participants to behave in line with what they assume to be the "demands" of the experimenter. No study, however, reported significant awareness of the intent to condition attitudes. Admittedly, these experimental cohorts differed from the real world public who view DTCA. Many participants were business or psychology undergraduates. However, these individuals can be expected to have a relatively sophisticated understanding of experimental psychology. Given their broad ignorance of the conditioning process, it is plausible that members of the general public would evince equivalent or lesser awareness of evaluative conditioning in DTCA.

Consumer Autonomy and Justified Beliefs About Material Facts

To understand the potential impact of implicit persuasion, exemplified by evaluative conditioning, on consumer autonomy, it is first necessary to mount a plausible theory of autonomy. The contemporary literature expounds many competing theories. Prominent among them are Hierarchical (Frankfurt 1971; Dworkin 1988), Life Plan (Young 1986), Historical (Christman 1991), Reasons-Responsive (Fischer and Ravizza 1998), and Relational (Mackenzie and Stoljar 2000) accounts. These theories are merely alluded to because the intention is to emphasize a commonality in each that has relevance for the current argument. While each account advances varying specifications for the kinds of desires that best underpin ascriptions of autonomy, each is dependent upon the agent holding a sound epistemology. Thus, it is largely uncontroversial that, should an agent wish to pursue decisions or actions that accord with deeply held desires, goals, or values, a grasp of pertinent facts is a necessary tool.

Perhaps the realm of medical ethics and informed consent has focused most attention on the epistemic requirements for autonomous choice. It is widely held that for patients to make fully informed and autonomous medical decisions, they must understand facts material to the treatment in question. Faden et al. (1986) provide insight into the nature of material facts. They argue that facts are material if they "would be viewed by the actor as worthy of consideration in the processes of deliberation about whether to perform a proposed action" (Faden et al., p. 303). Material facts are, therefore, those the individual considers important in making their decision about treatment. This "particular patient" standard of materiality is supported by legal precedent. In the Australian case Rogers v. Whitaker (1992), a woman sought a largely cosmetic surgical procedure to an eye that had been blinded in a childhood accident. The surgeon failed to warn her of the risk that surgery could rob her of sight in the functioning eye. This idiosyncratic complication, known as sympathetic ophthalmia, has a probability of 1 in 14,000. The complication occurred, and the judge commented that, objectively low odds aside, the patient's view that the risk was material was definitive.

Yet Faden and colleagues also make clear that for autonomy to be deduced, patients must not simply understand material facts, but also believe them (Faden et al., p. 311). Understanding that the physician asserts one's toe is gangrenous, for example, does not satisfy an autonomy standard if one remains committed to the belief the toe is just dirty. Here, understanding does not guarantee the fact of a gangrenous toe will be given due weight in the ensuing deliberations. But if belief is to be the relevant benchmark for autonomy, then epistemology offers two further potential standards: justified or true belief. True belief holds intuitive appeal – it seems obvious that a prospective patient must hold an accurate view of, say, the nature and site of an operation for autonomous consent to be proffered. Yet the true belief standard has drawbacks. A person with dementia may hold beliefs that alternate between the true and the fictional. If consent is obtained when the true belief is held, ought this to be seen as a moment of lucidity? Or is neurological deterioration merely throwing up vague semblances of reality? This is an example of "epistemic luck" which many philosophers eschew as grounds for legitimate knowledge.

In contrast, a justified belief standard emphasizes the reliability of the belief-forming process, where such a process enhances the likelihood that true beliefs will result. Goldman and Olsson (2008) provide an illustrative analogy. They describe a pair of scenarios in which a driver must negotiate two forks in the road to reach a town. In the first scenario, the driver has a reliable satellite navigation unit that, as expected, gives the correct direction at the first fork. In the second scenario, the driver has an unreliable navigation unit that, by chance, gives the correct direction at the first fork. Goldman and Olsson argue that, while drivers in both scenarios may hold a true belief about the correct direction at the first fork, the driver's belief in the first scenario carries greater epistemic value. That superior value stems from the fact that a reliable navigation unit heightens the

probability of a correct decision at the second fork, and ultimately reaching the desired destination. As the authors put it:

> [T]he conditional probability of getting the correct information at the second crossroads is greater conditional on the navigation system being reliable than conditional on the navigation system being unreliable (Goldman and Olsson 2008, p. 28).

This "conditional probability" thesis has relevance for autonomy in that most medical choices require not just one, but a suite of decisions in relation to a range of contingencies. For example, the decision to use a particular medication will require weighing its therapeutic efficacy against its side effects. The decision may also demand a comparison between the medication and alternative medicines, non-pharmacological therapies, or indeed no treatment at all. Should each belief derive from a reliable process, for example, a reading of evidence-based plain language information leaflets, there is a heightened probability of a true belief issuing at each juncture. By contrast, should the belief-forming mechanism be unreliable, a true belief may issue by chance in relation to one contingency, but the prospects are poor that outcome will be repeated. The result is a corruption of the deliberative process.

There are strong reasons to hold that evaluative conditioning in DTCA and other implicit persuasive techniques comprise unreliable belief-forming mechanisms that foster unjustified beliefs about pharmaceuticals. Moreover, many such beliefs will pertain to facts that are plausibly material to viewers with the relevant illness, such as the drug's safety and efficacy. Given a justified belief standard for autonomy, evaluative conditioning and related techniques pose a threat to autonomous drug choices. This threat is elaborated now.

Implicit Persuasion and Consumer Autonomy

Evaluative conditioning in DTCA is an inherently unreliable progenitor of beliefs about drug facts. To see this, it is first necessary to outline how evaluative conditioning influences belief. Evaluative conditioning employs valenced unconditioned stimuli to modify attitudes to a neutral conditioned stimulus. On a "tripartite theory" of attitude structure, the resulting attitude comprises affective, cognitive, and behavioral elements (Bizer et al. 2003). On this view, the transfer of positive valence from unconditioned to conditioned stimulus is accompanied by consonant beliefs about, and behavioral intentions toward, that stimulus. For example, if images of people enjoying themselves were used to condition positive attitudes toward an automobile, the tripartite theory predicts those attitudes to encompass positive beliefs, for example, that its components are of higher quality, and positive intentions, for example, a favorable disposition to purchase it.

There is empirical evidence of the impact of evaluative conditioning on belief. For example, Krosnick et al. (1992) used valenced imagery to condition positive and negative attitudes toward images of a woman studying and shopping. Participants conditioned to hold positive attitudes believed the woman to be friendlier, kinder, fairer, and more honest. Extending this research, Biegler and Vargas

(in preparation) found that participants conditioned (with positive imagery) to hold positive attitudes toward a hypothetical pharmaceutical believed it to be significantly safer, more effective, and more beneficial than did participants conditioned (with negative imagery) to hold negative attitudes toward the pharmaceutical.

Yet, it must be remembered that while the valence of an image used as an unconditioned stimulus influences belief about the conditioned stimulus, that valence bears no substantive relationship with characteristics of the conditioned stimulus. For example, the most positive valence image in the IAPS features three puppies perched expectantly on a wall. Should favorable beliefs emerge toward a co-presented pharmaceutical as a result of pairing with that image, there is no basis to conclude that such an effect will promote true beliefs. This is especially so should valenced stimuli be used with the intention of promoting favorable beliefs, at the expense of their veracity.

It may be countered that DTCA contains negative valence content and that positive conditioning plausibly corrects for this. For example, there is a requirement for extensive disclosure of side effects ranging from, for example, nausea and headache to life-threatening effects such as throat swelling or liver failure. Further, there is evidence that negative terms can act as unconditioned stimuli that can produce negative attitudes (De Houwer et al. 1994). On this view, positive imagery may be a necessary epistemic antidote.

It is conceded that such an effect may occur. The issue, however, is whether evaluative conditioning promotes true beliefs across a range of decisional instances. A person considering use of a medication, for example, an antidepressant, will be exposed to multiple advertisements for a range of drugs. Should evaluative conditioning occur in every ad, there is little chance that it will engender accurate beliefs in each case. It must be remembered that the primary intention of the technique is to persuade, not instill true belief, and so the latter will occur only haphazardly.

The relevance for autonomous choice is that such an unreliable influence upon beliefs about salient properties such as drug effectiveness and safety will surely lead to unjustified beliefs. And given that such properties are material to most who consider using a medication, autonomous choice is set back. Specifically, because unreliable belief-forming mechanisms heighten the chance of holding false beliefs, there is a lessened probability that drug choices will be in accord with the agent's values. Given the intense efforts in recent years to ensure that patients' decisions reflect a robust standard of autonomy, this effect of DTCA must give cause for serious circumspection about its permissibility, at least in its current form. That conclusion, however, faces an important objection that stems from the impact of recent psychological research on conceptions of human agency.

Implicit Persuasion and Agency

The argument thus far assumes a picture of human agency that sees agents as capable of rational deliberation and choice under conditions of sufficient information and absence of coercion or hidden persuasive factors. But what if this is hardly ever the case? And what if this picture of agency is mistaken?

One contemporary response to the concerns raised above about the effects on patient autonomy of implicit persuasion in DTCA is a skepticism about rational agency itself. This skepticism arises from a vast array of psychological data – some already referred to – demonstrating that we are largely unaware of many rapid and automatic influences on individual choice, judgment, and belief. These data suggest that, notwithstanding our beliefs to the contrary, individuals really have little idea of why they make the choices they do. Bargh and Chartrand (1999), for example, say:

> Most of a person's everyday life is determined not by their conscious intentions or deliberate choices but by mental processes that are put in motion by features of the environment and that operate outside of conscious awareness and guidance (Bargh and Chartrand 1999, p. 462).

For example, when subjects in a shopping mall were asked to make a choice between identical items on a stand, they showed a marked preference for the item on the right. But when asked to provide reasons for their choice, no subject mentioned this. Instead they produced explanations that focused on the supposed superior features of the product they chose (Nisbett and Wilson 1977, reported in Carruthers 2005, pp. 142–143).

According to a dual process model of cognition, many judgments that people make are the product of automated processing that occurs beneath the level of awareness. Indeed skeptics about the traditional picture of rational autonomous agency claim that *reasoning is not for what we think it is for*. It is not a vehicle for arriving at truth and securing autonomy in decision-making. Jonathan Haidt (2001, 2012) argues that its main function is to generate post hoc justifications for the intuitive judgments a person makes and to secure social agreement.

A skeptical view of the scope and role of conscious reasoning seems to make it more urgent to regulate persuasion in pharmaceutical advertising that operates below awareness, produces favorable product attitudes, and is not based on information. But there are at least two reasons to doubt this would make measurable difference to the quality of people's decisions. First, as Bargh and Chartrand (1999) note, the environmental influences on choice are numerous and varied. Our judgments have been found to be influenced by the weather (Schwarz and Clore 1983), by mood (Yuen and Lee 2003), by whether we are sitting at a clean or dirty desk (Haidt and Bjorklund 2008), and even by reading a report which uses plural rather than singular pronouns (Gardner et al. 1999). Positive imagery in advertising may have some influence on the beliefs people hold and the decisions they make. But it does not obviously follow that it makes their decisions worse or less autonomous than they would have been in the absence of such imagery. This is because the decision-making process is subject to many other unconscious influences which are likewise irrelevant to the properties of the product being evaluated.

Second, processing of purely *propositional* information is also subject to a range of cognitive and motivational biases which lead to incorrect beliefs. Persons are capable of more effortful and explicit controlled processing which can correct some of the biases to which we are subject. Kahneman (2011), however, argues that the controlled processing system is "lazy" and prefers to accept the deliverances of the

automatic system rather than to interrogate them. Jonathan Haidt (2012, pp. 83–88) surveys a range of evidence to support the view that when we do reason, the search for evidence is biased toward the conclusion we want to reach. Motivated reasoning, as it is known, selectively directs our attention to a subset of relevant information (Kunda 1990). Haidt argues that often a single piece of supporting evidence is sufficient to give us permission to believe what we want. For the purposes of considering the ways in which patients might process information in pharmaceutical advertising, two studies cited by Kunda (1990) stand out. First, subjects diagnosed as having a (fictitious) enzyme deficiency rated the condition less serious and the test less accurate than did subjects diagnosed as not having it (Ditto et al. 1988). Second, Kunda (1987) conducted a study in which subjects read a fictitious study claiming that caffeine was risky for women. Women with a high caffeine intake found the science less persuasive than women with a low caffeine intake or men. "Only subjects who stood to suffer serious personal implications if the article were true doubted its truth" (Kunda 1990, p. 489).

But even without such motivational influences on information processing, there is evidence that controlled effortful processing may not be the best way to arrive at important decisions.

> Conscious thought has shortcomings that can prevent sound decision making. First of all, conscious thought can lead to suboptimal weighting of the importance of aspects of different choice alternatives. In addition, because consciousness has *low capacity*, conscious thought often leads people to take into account only a limited subset of information at the expense of other information that should be taken into account when making a decision (Dijksterhuis and van Olden 2006, p. 628).

Lisa Bortolotti (2011) cites evidence suggesting that attitudes and choices arrived at via reason-giving are less optimal with respect to expert opinion and more vulnerable to evidence manipulation than those made without giving reasons (e.g., Wilson and Schooler 1991). This kind of evidence has been taken by both Jonathan Haidt (2001, 2012) and John Doris (2009) to show that the picture of persons as rational reflective agents is just false. It follows that *reasoning* (at least individually) is not a particularly reliable way to arrive at conclusions about what we have reason to do.

Thus, persons may not be the kinds of agents that they are assumed to be and careful reflection may not be a reliable way to get at the facts relevant to a decision. Further, decisions may be influenced by multiple and random persuasive factors in the environment of which individuals are not and cannot be aware, no matter how hard they try. From this, it might be argued that evaluative conditioning and other forms of implicit persuasion in DTCA do not leave patients in a worse epistemic and agential position than before. This may be especially the case given that mandated presentation of negative side effects in DTCA could lead to inflated assessments of risk.

Individuals have been found to overestimate the risk and prevalence of certain conditions. In addition to the powerful influence of framing effects on assessments of the risk and benefit of policies and actions – a scenario framed in terms of lives lost is evaluated more negatively than an identical scenario framed in

terms of lives saved (Tversky and Kahneman 1981) – the *alarmist bias* holds that "the worst possible scenarios loom large in people's minds, distorting their risk perceptions and their behaviours" (Kuran and Sunstein 1999, p. 706). As noted earlier, evaluative conditioning might correct such a distortion of risks and leave the patient in a better epistemic position than would the presentation of propositional content alone.

But evidence about the limits of rational agency and the need to counter irrational assessments of risk made by patients exposed to DTCA cannot constitute an argument for permitting implicit persuasion in DTCA. Rather it seems to constitute an argument against permitting DTCA at all.

Maybe in some cases, knowing the true reasons for, or causes of, our choices is not important. The fact that consumers tend to choose products on the right side of a display, and not because they are superior in the ways the consumer might reason, does not really matter. But, in many instances, getting it right does matter and so being aware of cognitive limitations and factors that shape deliberation outside awareness might be rather important. Choosing the medication most appropriate to a medical condition is something agents surely have reason to do and, as already argued, this choice ought to be responsive to facts about the medication and not to irrelevant features of an advertisement. However, given that human agency is systematically vulnerable to epistemically misleading influences, there is a need to consider what policies and practices support good decision-making, that is, decision-making in accordance with material facts.

One approach to the problem is social design. We can introduce nudges of various sorts to move us toward better decisions (Thaler and Sunstein 2009). Such nudges are common in health-related areas. They can include regulatory measures such as price signals, plain packaging of dangerous products, and warning labels. They also include government-sponsored advertising campaigns – for example, highlighting the dangerous effects of speeding, smoking, or excessive drinking. Such sponsored health campaigns, of course, often use similar persuasive techniques to those discussed here. They pair positive imagery with positive choices and negative imagery with dangerous choices. Do they undermine consumer agency or autonomy in so doing? If it can be argued that this use of implicit persuasion is benign because it nudges the consumer into a more accurate appreciation of the material facts relevant to a decision, could the same argument be available to pharmaceutical companies?

The obvious response to such claims is that there is no evidence that DTCA leaves us in a better epistemic and agential position and reasons to think that it does not. Whereas government health campaigns are motivated by paternalistic considerations, the goal of pharmaceutical advertising is neither paternalistic nor concerned with support for epistemic agency. Companies are motivated to increase sales and improve profits for shareholders. DTCA does so in part by implicit persuasive techniques and in part by providing explicit information that the evidence suggests consumers will be ill-equipped to evaluate. Its proponents claim that it enhances our agency by bringing more options to consumer attention. But if these options cannot be properly evaluated, consumers may be worse off.

A second approach to better decision-making is a reliance on experts. The account of the limitations of human agency and decision-making is at odds with an ideal of rational autonomous decision-making that is dominant in philosophy and bioethics. However, there are exceptions to this picture. Expert decision-making conforms more closely to ideals of agency in that it is less subject to the kinds of biases and distortions that plague the nonexpert, and more responsive to reasons and evidence. Lisa Bortolotti (2011) cites the following features of expertise identified by Hutton and Klein (1999). Experts in a domain are better able to perceive patterns; through years of experience, experts acquire the ability to perceive relevant features of the situation; their performance is virtually error-free; they display superior memory in their domain of expertise, have a deeper understanding of the problem to solve (e.g., they catch on to the causal mechanisms); they have a better understanding of their own limitations and an ability to catch themselves when they commit errors. It is important, however, to note that decision-making by experts does not usually require explicit reflection; it may be for the most part automatic or intuitive. Further, experts are by no means immune to the kinds of biases detailed here (Drew et al. 2013).

It should be apparent that many, or even most patients are not expert agents with respect to their medical condition or to pharmacology. If their decision-making in this important area is to count as autonomous, their agency must be supported by someone who *is* an expert and is bound to consider their best interests. Medical practitioners and pharmacists are the most appropriate candidates for this role. Pharmaceutical companies and advertisers are not.

At this point, proponents of DTCA may point to the important fact that a patient may become aware of a product for their condition via advertising, yet be unable to access it without a prescription. So their choice or preference must be discussed with a medical practitioner and their prescription must also be filled by a pharmacist. There will be an expert gatekeeper, and so their agency will receive appropriate scaffolding. It is appropriate then, to consider whether this is the case. How might the persuasive effects of DTCA on consumers impact the doctor-patient relationship?

Implicit Persuasion and the Doctor-Patient Relationship

A number of empirical studies have shown that DTCA significantly increases inappropriate prescribing (e.g., Mintzes et al. 2002; Murray et al. 2003; Gilbody et al. 2005). This increase seems largely because doctors working in DTCA environments face greater demands from patients for inappropriate medication, and because many doctors report that they find it difficult to resist such demands. As will be detailed, there is good reason to think that evaluative conditioning intensifies the impact of DTCA on inappropriate prescribing through such mechanisms. DTCA of pharmaceuticals also arguably undermines ethical medical practice in more subtle ways, as the impact of DTCA threatens to redefine therapeutic doctor-patient relationships as consumer relationships.

What do we know about the impact of pharmaceutical DTCA on doctor-patient relationships? Pharmaceutical companies invest heavily in DTCA, because, as noted above, it significantly increases sales. However, its mechanisms of influence over clinical practice have not been well understood as there was, historically, little systematic empirical research to substantiate various claimed effects of DTCA on doctor-patient relationships. More recently, however, a number of large-scale empirical studies have investigated those questions. For example, Murray et al. (2003) found that 74 % of the 535 US doctors they surveyed had seen patients in the previous 12 months who discussed DTCA drug information with them. Forty-eight percent of those patients were doing so because they wanted a change in medication, which in almost half of cases the doctor regarded as clinically inappropriate. The study also found that doctors "often seem to acquiesce to [clinically inappropriate] requests so long as the patient is not harmed" (Murray et al. 2003, p. 521). The researchers concluded that "DTCA results in patients making almost as many inappropriate requests as appropriate ones (Murray et al. 2003, p. 521)." In their 2004 study of patients, Murray and colleagues found that 161 of the 226 respondents who said they had discussed DTCA at a medical consultation requested a specific intervention or medication after viewing DTCA (Murray et al. 2004). Seventy of these respondents reported not receiving that intervention or medication from their doctor, despite requesting it (Murray et al. 2004, pp. 13–15). These findings raise ethical concerns about DTCA undermining patient autonomy in decisions about medicines, and jeopardizing beneficent action by doctors toward patients.

Similar concerns are raised by Mintzes et al. (2003). They surveyed 78 primary care physicians and 1,431 patients in Sacramento and Vancouver[1] about patient requests for specific drugs after exposure to DTCA for those drugs. The study found that 7.2 % of the Sacramento patients requested DTCA-advertised drugs, compared with 3.3 % of Vancouver patients (Mintzes et al. 2003, pp. 408–409). These findings are notable because patients' self-reported exposure to pharmaceutical DTCA was significantly higher in Sacramento than in Vancouver. Further, once a patient requested a drug, both the US and Canadian physicians were likely to fulfill such requests, but were particularly likely to do so when the request was for one or more DTCA drugs. The researchers reported that "In Sacramento 80 % of patients who requested prescriptions received them, as compared with 63 % in Vancouver. . .., Indeed, for patients requesting DTCA drugs, the odds of receiving a prescription. . .were 16.9 times those of patients who did not request a medicine" (Mintzes et al. 2003, p. 409). The researchers concluded that: "If DTCA opens a conversation between patients and physicians, that conversation is likely to end

[1]Although DTCA of prescription pharmaceuticals is prohibited in Canada, there has nevertheless been a proliferation of "reminder" or "branded" advertisements on television by Canadian pharmaceutical companies. These ads mention a brand name of a drug without specifying what condition the drug treats (see Silversides 2001) and are tolerated by Canadian regulators. Canadians may also view DTCA via US-based cable TV and the Internet.

with a prescription, despite frequent physician ambivalence about treatment choice. And the greater the patient's exposure to advertising, the more likely such a conversation will occur" (Mintzes et al. 2003, p. 412).

The first systematic review of the benefits and harms of DTCA concluded that, overall, "Direct to consumer advertising is associated with increased prescription of advertised products and there is substantial impact on patients' requests for specific drugs and physicians' confidence in prescribing" (Gilbody et al. 2005, p. 246). The same study corroborated the view that physicians often capitulate to patient demands for the advertised drug, despite physicians' misgivings about the drug in question. The strong influence of DTCA on patients making "brand-specific requests" following exposure to DTCA is also supported in the study of antidepressant requests cited earlier (Kravitz et al. 2005). The researchers trained actors to perform standardized patient roles to investigate the effects of patients' DTCA-based requests (and particularly brand-specific requests) for antidepressant drugs on doctors' prescribing behavior. Of 149 of these patients presenting with depression, 27 % of those who requested a specific brand of antidepressant received that drug. Of 149 patients presenting with adjustment disorder, for which medication is not a recommended treatment, 36 % of those patients had their brand-specific request fulfilled. The researchers concluded that "Brand-specific requests had a differentially greater effect in adjustment disorder compared with major depression. This supports the hypothesis that DTC advertising may stimulate prescribing more for questionable than for clear indications" (Kravitz et al. 2005, p. 2000). The authors also comment that "If patients can sway physicians to prescribe drugs they would otherwise not consider, physicians may not be the stalwart intermediary that the law assumes" (Kravitz et al. 2005, p. 2000). So, patients in DTCA environments seem to become more demanding of their doctors regarding prescription pharmaceuticals, and doctors often seem to give in to the pressures they feel from patients to prescribe a particular drug (see also Spurgeon 1999).

The effects of DTCA on inappropriate prescribing seem magnified when DTCA employs techniques such as evaluative conditioning to condition favorable attitudes toward the advertised drug. As argued in the first section, DTCA using evaluative conditioning undermines patients' ability to take an informed view about what medicines are best for them (see also Biegler and Vargas 2013). But there is also evidence that evaluative conditioning in DTCA influences patients to make brand-specific requests from their doctor.

A May 2012 study randomized 140 US undergraduate students to view either an actual TV commercial for a sleeping pill or read and hear a transcript of the ad's voiceover and printed statements (Biegler et al. unpublished study). The ad utilized positive valence imagery consistent with that used in evaluative conditioning studies. It also included a list of side effects, some of which are potentially serious. One dependent measure gauged the likelihood the participant would request the sleeping pill from a doctor if insomnia were experienced. Responses were recorded on a 7-point scale where 1 = extremely unlikely to request and 7 = extremely likely to request the pill from a doctor. Ad viewers' average rating of their likelihood of

requesting the sleeping pill was 4.47, compared with 4.13 (i.e., just above neutral) for transcript viewers. This difference was marginally significant, $F(1, 136) = 3.67$, $p = .057$. However, this difference was entirely driven by participants who were not native English speakers ($n = 51$); the marginal effect of ad condition on participants' likelihood of requesting the sleeping pill from their doctor depended on whether they were native English speakers, $F(1, 136) = 6.16$, $p = .01$. Non-native English-speaking ad viewers' average rating of their likelihood of requesting the sleeping pill from their doctor was 5.24, compared with 4.10 (just above neutral) for non-native English-speaking transcript hearers.

These findings support the persuasive power of the commercial's "nonpropositional content," that is, music, imagery, and voiceover tone, for example, that does not comprise an explicit claim about the drug. Nonpropositional content was differentially more persuasive for those less able to evaluate the ad's explicit, propositional claims. The findings buttress the ethical concerns already raised about the capacity of some DTCA viewers to accurately gauge an advertised medicine's properties and whether their subsequent requests for those drugs (often met by doctors) are in their best interests. Proponents cannot simply assume that DTCA is an unqualified good in terms of raising patient awareness of (and compliance with) medication, regardless of what method of advertising is used.

There is also good reason to hold that DTCA distorts the therapeutic nature of doctor-patient relationships. That is, DTCA threatens to redefine doctor-patient relationships as *consumer* relationships by altering the proper governing conditions of those relationships. Those governing conditions are demonstrated by what doctors *prioritize* in their clinical decisions, and by their *reasons* for prioritizing those considerations. For instance, a doctor who regularly prescribes drugs because they are demanded by patients responding to DTCA, whether or not the drug is optimal, demonstrates a consumer relationship rather than a therapeutic relationship with those patients (see Oakley 2012, 2014). The use of evaluative conditioning in DTCA heightens these concerns. This is because its persuasive potency will likely increase the frequency of such patient requests. Moreover, data on the resistance to extinction of evaluative conditioning suggests its presence in DTCA will make it more difficult for doctors to counter patients' ad-driven medication preferences (see Vansteenwegen et al. 2006).

These effects of DTCA are salient for policymakers tasked with helping professional medical associations meet their goal of preserving the therapeutic orientation of doctor-patient relationships. That goal faces the challenge of increasing commercialization of medical practice at a time when patients are becoming more forthright and assertive in relation to their health care. Thus, the Australian Medical Association's *Code of Ethics* advises that doctors should "Recognize that an established therapeutic relationship between doctor and patient must be respected" (Australian Medical Association 2006, Sect. 1.1.14). Allowing DTCA of prescription pharmaceuticals in countries such as the United States and New Zealand seems to have shifted many doctors' governing conditions from upholding patients' best interests, to meeting patients' brand-specific drug requests even when the request has questionable clinical merit.

Policymakers should be wary of the potential for DTCA to redefine doctor-patient relationships as consumer relationships. In return for being granted a monopoly of expertise on the provision of key goods, doctors are expected to have certain professional character traits. Doctors should be guided by a disposition to serve their patients' best interests and to prioritize patient welfare in their decisions. Doctors make a commitment on joining the medical profession to display a certain kind of professional character, one that, among others, maintains therapeutic rather than commercial relationships with their patients (see Oakley 2014). Even if DTCA were deemed beneficial on the grounds of health outcomes (though the cited evidence makes this unlikely) or perhaps by appeal to freedom of speech, its erosion of the therapeutic doctor-patient relationship is too great a moral cost to pay.

Conclusion

Research in social psychology increasingly shows that advertising persuades subtly, often outside of awareness. Evaluative conditioning is a well-researched implicit persuasive technique that plausibly operates in DTCA. There are good reasons to suppose that evaluative conditioning leads to more positive attitudes toward the advertised drug, and that such attitudes encompass inflated beliefs about drug safety and efficacy. Of grave concern, however, is that the positive imagery deployed to produce such conditioned beliefs bears little substantive relationship with properties of the advertised drug. Given the materiality of these drug properties for people contemplating pharmacological treatment, such an unreliable influence on belief will likely undermine their justification, and antagonize the autonomy of resulting medical decisions.

It is recognized that much recent empirical work in psychology and theorizing in the philosophy of agency raise serious questions about the extent to which conscious deliberation influences ultimate choice. Yet, as outlined, this work may not undermine the case against implicit persuasion in DTCA. Rather, given the augmented role for automatic processing in human choice making, greater efforts should arguably be made to prevent this system from being corrupted. Reduced exposure to implicit techniques such as evaluative conditioning presents as one means by which that end might be realized.

Nor is it sufficient to place the burden of preserving patients' autonomous choices on the physician gatekeeper. While the presence of that learned intermediary may mitigate heteronomous decision-making, strong evidence suggests it does so imperfectly. Physicians are vulnerable to pressure and persuasion from patients motivated, sometimes by wishful thinking, to realize their goal of pharmacological treatment.

On each of these counts, the emerging evidence of implicit persuasion as a driver of advertising effectiveness should counsel caution about DTCA. This should give reassurance to those many countries who outlaw DTCA. By contrast, the United States and New Zealand must widen their regulatory ambit to cover implicit persuasion in DTCA and encourage more research to delineate its effects.

Contents

Abstract

This introduction outlines the six chapters in the section "Development Neuroethics".

The neurotechnologies, treatments and enhancements of earlier Handbook sections are applicable to people of all ages. Few of the ethical dilemmas of research and clinical practice are specific to subjects or patients at a particular stage of life. Philosophical problems of mind, brain and identity are no more or less puzzling where children are concerned. Why, then, devote a separate section of a neuroethics handbook to developmental neuroethics?

One reason is that neuroethical issues that have been well explored in relation to adults often acquire new twists when the people involved are children. For example, where psychiatric treatment and enhancement are concerned, children's interests are generally entrusted to parents and other adults. This introduces new opportunities for conflicts of interest that we do not encounter with adults, involving for example the desire that parents and teachers may have for more peaceful homes and classrooms (▶ Chap. 106, "Neuroethical Issues in the Diagnosis and Treatment of Children with Mood and Behavioral Disturbances" by Johnston & Parens).

Neuroethical dilemmas may also play out differently in adults and children because the empirical facts of adult and child brain function differ. The greater sensitivity of young brains to environmental influence raises the issue of early interventions, when the individual's need for intervention may be less certain but

the likely effectiveness of it would be higher (▶ Chap. 107, "Prediction of Antisocial Behavior"). This same heightened plasticity argues for greater caution when intervening, for example with pharmacology or noninvasive brain stimulation (▶ Chap. 108, "Mind, Brain, and Education: A Discussion of Practical, Conceptual, and Ethical Issues"; ▶ Chap. 106, "Neuroethical Issues in the Diagnosis and Treatment of Children with Mood and Behavioral Disturbances" by Johnston & Parens).

Finally, some neuroethical issues are inherently linked to certain developmental stages. School takes up much of children's waking lives. It is therefore children who stand to be affected most by neuroeducation, and children who will bear the brunt of any premature or misguided educational practices it spawns (▶ Chap. 108, "Mind, Brain, and Education: A Discussion of Practical, Conceptual, and Ethical Issues"). The search for objective measures of cognitive development and neural maturity, to inform policies concerning children and adolescents and to determine to which individuals the policies apply (▶ Chap. 109, "Normal Brain Development and Child/Adolescent Policy"), is by definition linked to the young. Finally, childhood is the period when most psychological traits emerge, including atypical cognitive styles (Baron-Cohen ▶ Chap. 111, "Neuroethics of Neurodiversity"), gender identification (▶ Chap. 110, "Neuroscience, Gender, and "Development To" and "From": The Example of Toy Preferences" by Fine) and antisocial personality traits (▶ Chap. 107, "Prediction of Antisocial Behavior"). The neuroscience of these important individual differences are therefore rooted in childhood. Although the neuroethical issues raised in these cases are diverse, from biased interpretations of research data (▶ Chap. 110, "Neuroscience, Gender, and "Development To" and "From": The Example of Toy Preferences" by Fine) to the challenge of distinguishing between difference and deficit (Baron-Cohen, ▶ Chap. 111, "Neuroethics of Neurodiversity"), all exemplify the important work underway in developmental neuroethics.

Abstract

The number of children in the United States receiving psychiatric diagnoses and taking psychotropic medications rose significantly from the second half of the twentieth century through to today. Accompanying these increased rates of diagnosis and psychotropic medication use have come sometimes intense debates about whether the increases are appropriate, or whether healthy children are being mislabeled as sick and inappropriately given medications to alter their moods and behaviors. While these debates are in part highly technical, concerning questions in epidemiology and pharmacology, they are also infused with ethical questions about the appropriate goals of medicine, the nature of sickness and health, and the obligations we owe to children and families struggling to flourish. This chapter presents four inter-connected observations about the diagnosis and treatment of mood and behavioral disturbances in children that at least partially explain why this area generates concern and controversy, but that also point to important areas of agreement where progress can be made. These observations include that psychiatry can provide an important approach for understanding and responding to children's mood and behavioral problems provided we remember that it also carries its own complexities and difficulties. Further, forces within and outside psychiatry can influence how diagnoses are made and how treatments are selected, including systemic forces that strongly favor medication over psychosocial treatments, with the result that children too often receive pharmacological treatment only, even when other interventions are supported by evidence, contribute towards long-term flourishing, and reflect families' deepest value commitments.

Introduction

The number of children in the United States receiving psychiatric diagnoses and taking psychotropic medications rose significantly from the second half of the twentieth century through to today. A CDC report issued in 2013 estimated that 6.8 % of children aged 3–17 years living in the United States have a current diagnosis of attention-deficit/hyperactivity disorder (ADHD), with parents of 8.5 % of children reporting that they had ever been told that their child had ADHD (CDC 2013). While ADHD is by far the most widely diagnosed condition in children, parents report a current diagnosis of behavioral or conduct problems for 3.5 % of US children, anxiety for 3.0 %, depression for 2.1 %, and autism spectrum disorders for 1.1 %. As the CDC report also noted, almost 20 years' of surveillance show that these diagnostic rates have increased over time. Increases in diagnostic rates have been accompanied by increases in overall rates of use of psychotropic medications in children (Olfson et al. 2002; Zito et al. 2003), particularly antidepressants (Delate et al. 2004), stimulants (Safer et al. 1996; Habel et al. 2005), and anti-psychotics (Patel et al. 2005; Olfson et al. 2010).

Accompanying these increased rates of diagnosis and psychotropic medication use have come sometimes intense debates about whether the increases are appropriate, or whether healthy children are being mislabeled as sick and inappropriately given medications to alter their moods and behaviors (Timimi and Taylor 2004; Coghill 2004; Biederman 2005; Singh 2004; Conrad and Potter 2000; Olfman 2006; Jensen et al. 2006). While these debates are in one part highly technical, concerning questions in epidemiology and pharmacology, they are also infused with ethical questions about the appropriate goals of medicine, the nature of sickness and health, and the obligations we owe to children and families struggling to flourish.

Our chapter is organized around four inter-connected observations about the diagnosis and treatment of mood and behavioral disturbances in children that at least partially explain why this area generates concern and controversy, but that also point to important areas of agreement where progress can be made.

The First General Observation Is that Society Has an Obligation to Help Children Who Are Suffering from Mood and Emotional Disturbances, But that Deciding How to Help, and Delivering that Help, Can Be Practically and Politically Difficult

Although it is generally accepted that we should help troubled children there is controversy about *how* best to fulfill this obligation. Helping troubled children can involve making changes not – or not only – in the child herself, but also in her environment (her family, her school, her neighborhood, etc.). Children are deeply and tightly embedded in environments (or contexts) that can play a role in the emergence or severity of their mood and behavioral disturbances and, importantly, that can be key to their improvement. However, changing these environments can be practically difficult. For instance, it can involve changing classroom size, providing different kinds of instruction and classrooms, alleviating poverty, preventing home and neighborhood violence, changing parenting practices, and improving nutrition. It can also be politically difficult. For instance changing parenting practices, may be considered an intrusion on a matter of private choice. Helping parents, financially and in other ways, may raise questions about the just distribution of collective resources.

The Second Observation Is that Psychiatry Provides an Important and Powerful Approach for Understanding and Responding to Children's Moods and Behaviors, But that This Approach Carries Its Own Complexities and Difficulties

When children's mood and behavioral disturbances are understood as possible symptoms of a psychiatric disorder, the diagnostic categories and treatment tools of psychiatry can be used. In the US, this approach involves diagnosis with the American Psychiatric Association's *Diagnostic and Statistical Manual* (DSM).

The diagnostic categories in the DSM have been created over time by committees of experts, drawing on clinical experience and published research. The categories in the DSM are generally not based on an understanding of the pathophysiology of the clusters of symptoms they name, and most DSM diagnoses are made without the use of physiological tests (Nature Editorial 2010). Instead, a psychiatric diagnosis is today a judgment about whether a child meets the diagnostic criteria. The judgment is based on: the clinician's interpretation of the disorder's diagnostic criteria; the clinician's training and clinical experience; the clinician's observations of the child during the appointment; parents' and possibly teachers' and school psychologists' reports of the child's moods and behaviors; and, often, the results of a diagnostic instrument like a symptom checklist or structured interview.

Acknowledging the role of judgment, and the possibility of disagreements among clinicians, does not imply that childhood psychiatric diagnoses are not real. The clusters of signs and symptoms described in the DSM can cause real suffering in children (Hinshaw 1992; Barkley 2006) and real costs to families, the health care system, the education system, the juvenile justice system, and employers (through parental work loss) (Welham et al. 2007). Instead, it reminds us that psychiatric diagnoses are tools for thinking about the very real, varied, and sometimes deeply difficult lived experience of adults and children. Wielded thoughtfully, with awareness of their socially constructed nature, those categories can help to identify children who can benefit from intervention.

Several facts about the DSM approach help to explain why psychiatric diagnoses in general can generate debate and why that debate can be particularly acute when they are applied to children.

Children with Different Symptoms Can Receive the Same Diagnosis

For example, according to DSM-5, the essential feature of ADHD is "a persistent pattern of inattention and/or hyperactivity-impulsivity that interferes with functioning or development" (APA 2013). To receive the ADHD diagnosis, children must exhibit at least five or six (depending on the child's age) of the 18 core symptoms listed in the manual. The symptoms are divided into two major behavioral domains: inattention and impulsivity-hyperactivity. Among the nine symptoms of inattention: often making careless mistakes, often having difficulty sustaining attention in play or other activities, and often not seeming to listen when spoken to directly. A child exhibits some of the nine symptoms of hyperactivity-impulsivity if the child often fidgets or squirms, often cannot stay seated, blurts out, and has difficulty awaiting a turn. Different children can exhibit a different cluster of these 18 behaviors, but receive the same diagnosis.

Children with Some of the Same Symptoms Can Receive Different Diagnoses

For example, according to DSM-5, to receive a diagnosis of classic or full-blown bipolar disorder (bipolar I), the individual must experience a manic episode, which is

"a distinct period of abnormally and persistently elevated, expansive, or irritable mood" lasting for at least 1 week. If the patient's mood is elevated or expansive she must exhibit at least three of the following seven symptoms: (1) grandiosity, (2) decreased need for sleep, (3) pressure to keep talking, (4) flight of ideas and racing thoughts, (5) distractibility, (6) increased goal-directed activity and psychomotor agitation, or (7) excessive involvement in pleasurable activities that have a high potential for painful consequences. If the patient presents with irritability, she must exhibit at least four of those seven symptoms. At a minimum, three of the symptoms used to diagnose bipolar disorder are very similar to those used to diagnose ADHD: pressure to keep talking, psychomotor agitation, and distractibility. If one adds into the mix the symptoms of oppositional defiant disorder (ODD), which is frequently characterized by irritable mood, it can be difficult to determine whether bipolar disorder, ADHD, or ODD – and now Disruptive Mood Dysregulation Disorder (DMDD) – is the best-fitting diagnosis. In practice, one result of this overlap is that children showing a mix of symptoms often receive more than one diagnosis (and are treated with more than one medication). Another result is that children who exhibit some of the same symptoms may receive different diagnoses.

Symptoms of the Same Disorder Can Look Different in Children and Adults

Unlike its predecessor, DSM-5 does not contain a special section of disorders usually first diagnosed in infancy, childhood, or adolescence, but instead integrates diagnoses most applicable to children throughout the manual by placing them at the beginning of diagnostic chapters (e.g., the first disorder listed in the Anxiety Disorders chapter is Separation Anxiety Disorder). Despite this integration, clinicians may still diagnose children with disorders usually reserved for adults (or vice versa), which may require adapting the diagnostic criteria. Two examples of this adaptation process can be seen in depression and bipolar disorder. Before the 1970s, clinicians theorized that, while children could experience transient sadness, they were not sufficiently emotionally developed to experience clinical depression (Abela and Hankin 2008). By the 1980s, researchers argued that children can experience depression, but that depressive symptoms can take slightly different forms in adults and children. For example, while adults may experience depressed mood and significant loss of interest in activities, small children may be more inclined to show particularly severe separation anxiety, while restlessness, sulkiness, and withdrawal from social activities might be more pronounced in adolescents (Kashani et al. 1981). Today, the idea that children can experience depression and that their symptoms may be different from those seen in adults is fairly uncontroversial within psychiatry, even if there remains some debate about how best to treat it (March and Vitiello 2009).

The story of the diagnosis of bipolar disorder in children is quite different. While it is widely agreed within pediatric psychiatry that some rare children exhibit discrete episodes of mania and meet full DSM criteria for bipolar disorder, much of the controversy in the United States over the past decade

has been rooted in disagreements about whether it can look *very* different in children and adults. Beginning in 1995, some researchers began to argue that *chronic* irritability (or raging) was a symptom of mania in children, even though in adults clinicians look for *distinct* episodes of "abnormally and persistently elevated, expansive or irritable mood" (APA 2013). That argument was highly contested, although it is not theoretically implausible. A subset of adults with bipolar say that their symptoms went unnoticed when they were children and children's bodies are developing and are different from adults', so it is conceivable that prodromal symptoms of a disorder, including bipolar disorder, or symptoms of the full-blown disorder itself, could look quite different in children and adults. However, in the case of bipolar disorder, which began to be much more frequently diagnosed in children during the 2000s, some researchers argued that the symptoms at issue, in particular chronic irritability, are best understood as markers of a different disorder altogether. In 2003, one team began using the term "severe mood dysregulation" to describe these children (Leibenluft et al. 2003), and in 2013 DSM-5 introduced the new diagnosis of "Disruptive Mood Dysregulation Disorder (DMDD)" for children exhibiting severe recurrent temper outbursts in response to common stressors (APA 2013). It is not yet known the extent to which DMDD will replace previous diagnoses of bipolar disorder in children.

Careful Diagnosis Requires Both Identification of Symptoms and Evaluation of Impairment

DSM-5 is clear that the presence of symptoms alone seldom warrants a diagnosis; a diagnosis is warranted when symptoms create significant impairment. Some impairment might be inferred from the fact that parents make appointments with health professionals, but impairment assessments are unfortunately not always included in diagnostic work-ups. When they are included, diagnostic rates are lower. In one study, researchers assessing a sample of children for serious emotional disturbances found prevalence rates of between 4 % and 8 %, depending on which of three different impairment measures was used, and a prevalence rate of 20 % when impairment was ignored (Costello et al. 1996). Reimbursement systems, which require a DSM diagnosis, may indirectly encourage clinicians to record a diagnosis even when the severity criteria are not fully met, in order to justify the provision of services.

The Diagnostic System Does Not Encourage Assessment of the Child's Context

In the context of depression, Allan Horwitz and Jerome Wakefield have argued that "the basic flaw" of the DSM approach is that it "*fails to take into account the context of the symptoms*" (Horwitz and Wakefield 2007). Writing about

depression as defined in DSM-IV, Horwitz and Wakefield noted that only intense sadness in response to the death of a loved one was listed as a context-specific reaction that should not count as a symptom, whereas myriad other sorts of normal human problems that could also trigger intense sadness – from the lack of strong, meaningful attachments to job loss (in adults) to being bullied or neglected (in children) – went unmentioned. As a result, Horwitz and Wakefield argued, people who are intensely but appropriately sad due to life events or circumstances can mistakenly receive a diagnosis of depression. (They are thinking primarily of adults, but the same analysis applies to children.) Their complaint would likely be even stronger now that DSM-5 has removed the bereavement exclusion from the definition of depression (Wakefield 2013).

Robert Spitzer, the head of the American Psychiatric Association's DSM-III task force, has similarly noted that the definition of mental disorder offered in the *introduction* to the DSM clearly states that mental disorder involves dysfunction or impairment that is not an expectable or proportionate response to a common human problem or stressor, but the diagnostic criteria used in the *body* of the manual – the part that clinicians usually consult – rarely mention the need to consider contextual explanations for symptoms. According to Spitzer, this arrangement allows "normal responses to stressors to be characterized as symptoms of disorder" (Horwitz and Wakefield 2007). By failing to discuss contextual explanations for problematic moods and behaviors, the manual can seem to suggest that context is irrelevant to diagnosis and treatment decisions. This apparent failure is particularly important when dealing with children. If a child's moods and behaviors are an adaptive or appropriate response to her adverse, traumatic, or otherwise difficult context, it could be a serious mistake to treat the child but fail to make changes to her environment. But it is also important to remember that a contextual explanation does not by itself indicate that the child is not suffering from a mental disorder. Just as a child whose fever results from drinking unclean water needs both a fever medication *and* an improved water supply, so an abused child suffering posttraumatic stress disorder (or another condition likely linked to their abuse) may be helped both by treatment (pharmacological and/or psychosocial) and changes to her environment.

Symptoms and Impairment Are Dimensional, and Children Are Developing Organisms

The introduction to DSM-5 acknowledges that psychiatric diagnoses refer to phenomena that are *dimensional*, but the body of the text uses *categories* to name them. This tension is acknowledged by the manual's authors, although in the end they conclude that it is "premature scientifically to propose alternative definitions for most disorders" (APA 2013). When the DSM-5 authors use "dimensional" in the introduction, they refer to the fact that symptoms appear on a continuum of

expression or intensity, and that so, too, can disorders. Individuals who, for example, exhibit a single symptom such as excessive worrying can do so to different degrees. And individuals who exhibit a cluster of symptoms indicative of anxiety disorder can also do so to different degrees, which can produce different degrees of impairment.

Determining whether a given child's moods and behaviors are intense enough to be labeled disordered is further complicated by the fact that, as still-developing organisms, their moods and behaviors can be very different from those we see in adults and can vary greatly depending on the age of the child (it may be normal for a 4-year-old child to talk with an imaginary friend, but not for a 14-year-old or an adult) (McClellan 2005). Indeed, the experiences of children who do and do not live "under the description of" a psychiatric disorder, as the anthropologist Emily Martin wrote in 2007, are not always as radically different as the categorical labels can seem to suggest. This dimensionality is not unique to children, or to psychiatry. There is also a continuum between adults who do and do not warrant a diagnosis of, for example, hypertension. But because our moods and behaviors are closer to our sense of identity than a trait like blood pressure, and because recognizing these moods and behaviors as symptoms of a disorder requires greater observer interpretation than reading blood pressure results, our values play a bigger role in determining where to draw the line on the anxiety continuum than on the blood pressure continuum.

Diagnostic Categories Create a "Zone of Ambiguity"

Because of this dimensionality, there will be significant agreement that some children are on one end of a continuum and need help in changing their impairing moods and behaviors, and that other children are closer to the middle of that continuum and deserve to be affirmed in their atypical-but-not-impairing ways of being. Or, in more colloquial parlance, there will be ready agreement that some atypical children are sick and that other atypical children are healthy. However, there will be a sizable "zone of ambiguity" between those uncontested regions of the continuum, in which reasonable people may well disagree about where to draw the line between normal and disordered, about whether or not a given child is suffering from a disorder. This disagreement may result from differences in knowledge about, or experience of, children and their moods and behaviors, but it can also result from differences in the underlying value commitments of these reasonable people. Some may have an expansive conception of disordered behavior, and others may have an expansive conception of normal variation. Acknowledging the existence of this zone of ambiguity and the role that value commitments play in diagnostic decisions made within this zone does not undermine the seriousness of the problems that families and children experience (although it can sound that way to some who deal with these problems day to day (Resko 2011)).

The Third General Observation About the Ethical Issues Surrounding the Treatment of Troubled Children, Is that Values Play an Ineliminable Role in the Creation of Diagnostic Systems, the Diagnosis of Individual Children, and in Treatment Decisions

Again, recognizing that judgment and therefore values play a role in the creation of diagnostic categories does not diminish the potential harmfulness of the moods and behaviors at issue, nor imply that those categories and treatments are arbitrary or useless. Instead, it forces us to be clear about the extent to which medicine, including psychiatry, is socially constructed.

People can, as a result of different value commitments, hold different views about how narrow or broad the goals of pediatric psychiatry should be. When a child's symptoms land her in the zone of ambiguity, those differences can affect diagnosis. Psychiatry is not unique in harboring disagreements about how narrow or broad our conceptions of illness and health should be – nor about how cautious or aggressive our treatment approaches should be. Some observers are untroubled by the tendency of medicine in general – and psychiatry in particular – to treat problems that seem to have their proximate cause in educational, social, or cultural mores rather than in pathophysiological dysfunctions. Such observers can argue that, insofar as the goal of medicine and psychiatry is to promote the well-being of persons, and insofar as what counts as well-being always depends on functioning in a particular time and place, there is no reason to be alarmed if psychiatrists aim to help people to function – or even to excel – in this particular time and place (Greely et al. 2008). Other observers are alarmed by this tendency. They suggest that these expanded goals and lowered diagnostic thresholds pose risks to individuals and society (Conrad 2007). Critics of 'medicalization,' as it has been called by Peter Conrad, are concerned that it is too often fueled not by the needs of patients but by drug companies, which profit by creating or expanding disorders for which they then market medication treatments, even where the medications have limited efficacy and carry the risk of serious side effects (Conrad 2007; Sadler et al. 2009; Sadler 2007). Others, like William Carey, are concerned that we are losing touch with what is normal for children or that the definition of normal in children is getting narrower and narrower for the convenience of adults and not the best interest of children (Carey 2011). Conrad, Carey, and others demand that we recognize that a wide range of human temperaments and behaviors are compatible with a healthy human life (Carey and McDevitt 1995).

Whether one is more or less distressed by medicalization of children's moods and behaviors can partly depend upon the extent to which one emphasizes one of two deep obligations that parents must constantly balance (Parens 2006). On the one hand, parents have an obligation to let their children unfold in their own ways, to affirm them as individuals and to let them be who they are. The violin-loving father who pushes his football-loving son to play the violin fails to accept his son and affirm his son's pursuit of what seems good to him. On the other hand, parents

have an obligation to shape their children through discipline, education, and adherence to traditions. A parent who lets her child stay home all day every day to play video games violates her obligation to shape her child.

Though both obligations are fundamentally important, it is inevitable that in particular situations some parents will emphasize one over the other. Parents who emphasize their obligation to shape their children may be fairly quick to see intervention in the zone of ambiguity as just one more instance of fulfilling that obligation – even though they accept that they also have an obligation to let their children unfold in their own way. Other parents will be more inclined to let their children unfold in their own ways and will therefore be reluctant to see their children's moods and behaviors as potentially "disordered" and in need of psychiatric assessment.

The situation can be similar when choosing which *means* to use to treat a child. Few dispute that medication should play a role in the treatment of children with classic bipolar disorder, and few dispute that behavioral therapies should play a role in the treatment of children with depression (Whittington et al. 2004). Yet as we found in the case of ADHD, disagreement can occur when the data on the efficacy of various treatments is unclear (Fabiano et al. 2009; UK NICE 2008; Schlander 2008). In the face of this complexity and disagreement, parents and clinicians may prefer one or the other means of treatment not simply because of what clinical trials have shown about its safety and effectiveness, but because it best fits their preexisting value commitments.

For example, medications tend to emphasize the value of *efficiency* insofar as they are often quicker acting, cheaper in the short term, and require less time to administer than psychosocial treatments. They can quickly improve a child's symptoms so that she can return home from hospital, return to school, or return to her regular activities. Behavioral interventions, on the other hand, tend to emphasize the value of *engagement*, by requiring parents, peers, teachers, or therapists to work with the child and with his environment (Parens 1998). Because behavioral interventions seem to locate the "problem" in the interaction between the child and her home, school, and social context rather than in her body, they can prompt us to notice the importance of the child's environment and take steps to improve it, and they may help the child learn to think of herself as a moral agent, as someone who can learn how to change. While some parents and clinicians will favor the value of efficiency and others will favor the value of engagement, most will acknowledge the importance of both values, just as they appreciate both the obligation to shape children and the obligation to let them unfold in their own ways.

Recognizing that some disagreements about how to define mental disorders, and how to diagnose or treat a given child, can arise because reasonable people emphasize different but equally respectable values in no way minimizes the enormous social and economic pressures bearing on families to emphasize some value commitments rather than others. Nor does it in any way minimize the need to distinguish between reasonable disagreements and mistakes.

In a perfect world, the debate about diagnosing and medicating children would be about how best to balance these different value commitments. But too often in the United States, diagnostic and treatment decisions are driven and constrained by the broader culture and the institutions and systems in which parents, children, and clinicians must operate.

The Fourth and Final Observation Concerning the Diagnosis and Treatment of Childhood Mood and Behavioral Disturbances Is that a Number of Social and Economic Forces Shape Diagnosis and Constrain Treatment Choice

In particular, these forces systematically favor pharmacological over psycho-social interventions. In part because of this, many children do not receive careful diagnoses, evidence-based treatments are often not available, and promising changes to children's environments are not made. Many aspects of current biomedical research funding and healthcare economics shape the diagnosis and treatment of troubled children. Several of these will be reviewed here (see Parens and Johnston 2011 for a more complete discussion).

To begin with, the treatment marketplace is dominated by psychotropic medication, despite evidence supporting the safety and effectiveness of some psychosocial treatments for particular disorders. One reason for this dominance is spending on drug development and testing far exceeds spending to develop and test psychosocial treatments (DiMasi et al. 2003; Adams and Brantner 2006). In addition, psychotropic drug treatments are aggressively marketed to practitioners and patients (Gagnon and Lexchin 2008). This is true despite ongoing concerns about the drug approval process and, therefore, about drug safety and effectiveness (Okie 2005). These concerns are not limited to drugs used to treat children diagnosed with mental disorders, but given underlying worries about the impact of medication on the developing brains and bodies of children and the heightened ethical obligations that physicians and parents have to minors for whom – or with whom – they are making treatment decisions, the concerns take on a particular urgency in this context (Zito et al. 2008).

Changes that would begin to redress the imbalance between investments in the development of new pharmacological compared with psychosocial treatments include sustained or increased government and philanthropic funding of basic research likely to lead to new psychosocial interventions, and of clinical research to test their effectiveness once developed. Once new, evidence-based psychosocial treatments are available, funds will be required to market these treatments and to train practitioners to use them effectively. Changes that would begin to improve the information available about medication treatments as they are actually used in the community include enabling the FDA to require robust post-marketing registries on selected medications that are used in children.

Several features of U.S. health care increase the likelihood that diagnostic mistakes will occur and that psychotropic medications alone will be the default treatment for children's mood and behavioral disturbances. Several of these features are causes for concern in themselves because in addition to limiting clinicians and parents' choices, they suggest that children are not receiving recommended care (Druss 2011).

In general, visits to medical practitioners are very brief. Although one study showed that pediatricians spent an average of between 5 and nearly 7 min longer with patients when behavioral health concerns were raised than when they were not (Cooper et al. 2006), visits including behavioral health concerns are still likely to last less than 20 min. It is extremely difficult in such a limited time for practitioners to undertake careful mental health diagnoses; reassess these diagnoses; discuss and reassess medication treatments; or provide and monitor psychosocial interventions. Not only are these visits of short duration, but they are less frequent than is necessary for optimal treatment management.

With respect to providers, the system is fragmented among primary care physicians, hospitals, and various other mental health care providers, as well as other systems that care for children, including child protective services, juvenile justice, and schools (Foy and Perrin 2010). Practitioners and parents seeking psychosocial interventions have limited ability to identify services, judge their quality, or assess the expertise of individual practitioners. Primary care providers have limited ability to monitor the costs and outcomes of any psychosocial interventions they recommend. When psychosocial services are identified, long waiting lists often delay access, and high rates of staff turnover among mental health providers can disrupt continuity of care. Families who are committed to psychosocial treatments may be left to identify, access, and navigate them alone (Olfson and Marcus 2010).

Where mental health care is funded through private insurance, coverage for psychosocial treatments is often more limited than for medication treatments (Teich and Buck 2007), despite new legislation (Druss 2011). Under managed care plans, medication treatments for emotional and behavioral disorders do not count as behavioral health care costs, but instead fall under the plan's general prescription drug coverage (Frank et al. 2005). Behavioral health care management organizations, therefore, have an incentive to reduce utilization of psychosocial treatments (and hospitalization), but they are unaffected by the use of psychotropic medications. They may further restrict reimbursement for psychosocial interventions by requiring the presence of the patient at each treatment session, which means that they do not cover parent training, for example, which is known to be effective but does not require the presence of the child.

Conclusion and Future Directions

Some of the complexities associated with the current approach to diagnosing emotional and behavioral disturbances in children have been described. Most of the diagnoses articulated in the DSM were based on observation of symptoms in

adults, but symptoms of what psychiatrists consider to be the same disorder may look different in adults and children. Also, the DSM's categories capture heterogeneous phenomena, and they overlap; further, because symptoms and impairments are expressed along continua, there are no bright lines between healthy children and those who warrant diagnoses.

Informed, trained, caring people will thus sometimes have reasonable disagreements about where to set diagnostic thresholds and about whether a mildly affected child – a child in the "zone of ambiguity" – would benefit from a diagnosis. These disagreements can occur when people have different value commitments or just give different emphases to shared value commitments (regarding, for example, the goals of psychiatry or the goals of parenting). Such value differences or emphases can play out in the context of treatment decisions as well.

Nevertheless, some conclusions are widely accepted. For one thing, there is agreement that children can indeed have serious psychiatric disorders and that medications can be an essential part of appropriate treatment plans. For another, no matter how important it is to tolerate reasonable disagreements, it is essential to avoid the sorts of mistakes that involve patent over-diagnosis, misdiagnosis, and under-diagnosis, which result in many children not receiving the care they need. These mistakes are facilitated by systemic forces that bear on clinicians and families and restrict the time available for careful diagnoses. Specifically, these forces can make it tempting to base a diagnosis on the presence of symptoms alone, as opposed to doing the sort of careful evaluation that can determine whether those symptoms impair the child and what role, if any, the child's context might play in causing their distress. Those same systemic forces strongly favor medication treatments over psychosocial ones, so that children too often receive pharmacological treatment only, even when other treatment plans are supported by evidence, contribute towards long-term flourishing, and reflect their or their family's deepest value commitments.

Abstract

A growing body of evidence suggests that biological factors such as genes, hormone levels, and brain functioning are associated with antisocial behavior. As research progresses, we will likely develop a better understanding of how biological factors very early in life influence the development of antisocial traits. This attempt to identify genes and early biological indicators of

a propensity for criminal behavior raises a number of ethical concerns. In this chapter, the idea of an early destiny to crime is refuted and an attempt is made to explain the limited role that biological research alone has in predicting future criminal acts while the important potential that it has for helping us solve this significant societal problem is emphasized. It is argued that current knowledge on biological risk factors does not allow us to predict with reasonable certainty whether an individual is going to commit a crime. However, biological information may provide useful information about which individuals may be at somewhat greater risk for antisocial behavior, and thus may provide for the opportunity to intervene with programs designed to reduce this risk. A discussion of the ethical implications of this research is made at the end, including the potential for false positives, concerns about stigma, and the role of informed consent and the rights of children and parents.

Introduction

Some have suggested that biological research on crime may open the door to discrimination based on genes or brain indices, or that it may lead to individuals being labeled or punished before they have committed any crime. Media headlines such as "Criminal Behavior May Be Hard-Wired in the Brain, Researchers Find" (*Los Angeles Times*, November 17, 2009) perpetuate the idea that the identification of biological influences on criminal behavior indicates that some individuals are irreversibly destined for a life of crime. It is argued that many of the strong reactions to biologically based research may stem from a misunderstanding of the purpose of this type of research and the limitations of it in crime prediction. It is important to note that studies examining biological risk factors, like studies of environmental risk factors, represent *average* differences between groups. This means that there is no one-to-one relationship between biological factors and crime; many individuals with risk factors will not go on to commit crime, whereas some individuals who do not demonstrate a particular risk factor may proceed to commit crime. In other words, none of the studies produce large enough effects that alone would accurately predict who will grow up to be an offender. Furthermore, in most cases – as with social constructs – it has not been established that these biological risk factors are causal. Finally, the concept of multifinality comes into play. A wide range of biological and environmental factors may contribute risk for antisocial behavior. Thus, not all antisocial individuals will demonstrate the same biological (or environmental) deficits.

A start is made with an overview of genetic, electrophysiological, neuroendocrine, and neuroimaging measures that have been identified as early predictors of antisocial behavior. What the research in these domains can and cannot tell us about the risk for criminal behavior will be discussed.

Genetics

The idea that antisocial or criminal behavior is heritable is one that has been very controversial over the years. It has been alleged that examining the genetic factors that may contribute to crime is similar to "the kind of racist behavior we saw on the part of Nazi Germany" (Palca 1992). This reaction reflects a misunderstanding about the relationship between genes and behavior, and also a failure to recognize the potential for genetic research in aiding the development of positive outcomes, such as improved prevention and intervention methods.

Twin and adoption studies have provided significant scientific evidence that there is a substantial genetic contribution to criminal behavior (Moffitt 2005; Raine 2008). Genes are thought to account for approximately 50 % of the variation in criminal behavior across individuals in the population (Ferguson 2010). However, there is no single gene, or even a small group of genes that currently enables us to predict which individuals will commit crime in the future. The association between a single gene and a behavioral tendency or trait is typically very small (Canli and Lesch 2007). This is due to the fact that the pathway from a single gene to behavior is complex, and countless additional factors are introduced at each step. For example, environmental factors can alter the way that genes are expressed (e.g., turning genes "on" or "off"). This suggests that being a carrier of a particular gene does not necessarily mean that the functions of that gene will be realized. For example, animal studies have found that separating rat pups from their mother during the first 3 weeks of life results in increased expression of a gene associated with stress hormones in the hippocampus and prefrontal cortex, two brain regions which are critically involved in regulation of the stress response. Behaviorally, the rats demonstrated fearlessness and a blunted stress response in adulthood (Weaver et al. 2006), characteristics which are observed in some antisocial individuals and are thought to contribute to reduced sensitivity to punishment and blunted emotions. This documents that environmental factors early in life, such as maternal behavior, can directly change gene expression, thus altering the way in which the brain develops, and altering subsequent behaviors. Thus, the link between any particular gene and a behavior depends on the environmental context. Furthermore, the functioning of a particular gene may also depend on the presence of other genes.

The idea that the contribution of a single gene to complex behavioral traits is very small was demonstrated in a recent genome-wide association (GWA) study (Viding et al. 2010). GWA studies scan the genome for polymorphisms that may be more common in one group (e.g., individuals with persistent antisocial behavior) versus another (e.g., individuals without antisocial tendencies). Viding et al. (2010) used this method to attempt to identify genes that may be more common in children scoring high on both callous-unemotional traits and antisocial behavior, both of which are predictive of later aggression and delinquency (Frick et al. 2003). The study, which was powered to detect genes of large effect size, did

not find any genetic associations that reached genome-wide statistical significance (i.e., accounting for more than 1 % of the variance). This suggests that there is not going to be a single gene that will account for a large proportion of the variance in criminal behavior.

In addition to studies looking across the whole genome, studies have also examined the effects of specific gene variants that are hypothesized to be associated with antisocial behavior. These studies require very large sample sizes in order to detect any effect, because the effect of a single gene accounts for such a small proportion of the variance in the behavior (Lesch et al. 1996). In addition, many of the gene variants examined are very common in the population. For example, 20–35 % of individuals may be carriers of a particular "risk" genotype. Although the gene may significantly increase the risk for something such as persistent antisocial behavior, the majority of individuals with this particular gene variant do not become persistent criminals. Furthermore, many of these findings are limited to particular circumstances (e.g., the finding only applies to males, or only to individuals of low socioeconomic status). For example, Caspi et al. (2002) found that a variant of the monoamine oxidase A (MAOA) gene increased risk for antisocial behavior only in individuals who had experienced severe maltreatment as children. This gene-environment interaction emphasizes the idea that many factors are involved in the pathway from genes to behavior. Some genes may essentially sensitize children to environmental insults. Because the context in which genes operate varies from person to person, it would be not possible to use genetic information alone to predict whether an individual will commit a crime. However, what we may be able to do is identify youth who may be particularly sensitive to environmental risk factors, and try to change their environment in positive ways.

In sum, the genome overall exerts a substantial influence on criminal behavior, but no single gene is a major determinant. Whether any particular gene contributes to the risk for criminal behavior depends on the influence of environmental factors and other genes. Environmental factors such as poor nutrition, severe parental neglect, sustained physical and sexual abuse, early head injuries, learning disabilities, a family history of mental illness, poor cognitive functioning, toxin exposure, and a lack of parental supervision may all interact with genetic predispositions to increase the risk for antisocial behavior. By enriching the environment and/or reducing the presence of negative environmental factors such as childhood abuse, we may be able to reduce the influence of these genes on the development of traits related to antisocial behavior.

Psychophysiology and Neuroendocrinology

A number of studies have found that biological indicators early in life are predictive of later criminal behavior. For example, in a longitudinal study, Gao et al. (2010) compared individuals who had a criminal conviction at age 23 with individuals who did not have a conviction. Looking back at the results obtained 20 years earlier,

these two groups differed at age 3 on a test of fear conditioning, that is, the degree to which they developed a fear response to neutral stimuli that were repeatedly paired with aversive stimuli. Those with a conviction demonstrated relatively poorer fear conditioning at age 3 than those who did not. This suggests that poor fear conditioning at age 3 may act as a risk factor for future criminal behavior. Additional predictors of aggressive behavior were also observed in this sample. For example, low heart rate at age 3 years was found to predict aggression at age 11 years in children from high but not low social classes (Raine et al. 1997). Individuals with higher skin conductance orienting responses at age 3 were found to score higher on a self-report psychopathy scale at age 28 (Glenn et al. 2007). Psychopathic traits consistently have been found to predict offending (Grann et al. 1999; Gretton et al. 2004; Salekin et al. 2003).

Biological factors in adolescence have also been found to be predictive of later antisocial behavior. Tarter et al. (2009) found that increased levels of the hormone testosterone at ages 10–12 predicted assaultive behavior at ages 12–14, norm-violating behavior at age 16, and cannabis use at age 19. In another longitudinal study on delinquent male adolescents, attenuated heart rate response and stronger heart rate variability response to stress predicted higher reoffending rates 5 years later (de Vries-Bouw et al. 2011). Using electroencephalogram (EEG), Raine et al. (1990) found that indicators of early attentional processing at age 15 predicted criminality status at age 24. Arseneault et al. (2000) showed that minor physical anomalies, indicators of fetal neural maldevelopment, measured at age 14 years in 170 males predicted violent, but not nonviolent, delinquency at age 17 years.

These studies demonstrate that many individuals who go on to commit crime demonstrate biological differences early in life. By understanding how these biological risk factors interact with social and environmental risk, we may be better able to understand the development of criminal behavior.

Brain Imaging

Because brain imaging is a relatively new method, to the authors' knowledge, no studies to date have used the prospective longitudinal design discussed in the previous section to examine the neurobiological differences early in life that may confer risk for later criminal behavior. Thus far, the majority of studies conducted have been cross-sectional, examining differences in the brain in antisocial individuals compared to controls. As research currently stands, in the absence of gross impairments due to head injury or disease, claims about individual subjects cannot be made. Although effect sizes in brain imaging studies may be quite large, cut-off points at which it would be said that a particular individual demonstrates "abnormality" in a particular brain region are not yet determined. However, as research progresses, it may be able to quantitatively identify more specific neurobiological differences that increase the risk for antisocial behavior. By building up normative databases, it may be possible to create objective measures of brain structure or functioning that indicate a particular level of risk for antisocial behavior.

Like environmental and other biological risk factors, although it is unlikely that brain imaging could be used to predict *specific* criminal events, it is plausible that it could provide information about risk of recidivism. Indeed, two recent studies have found that information gained from brain imaging was predictive of future offending. In a sample of adult offenders, Aharoni et al. (2013) found that low activity in the anterior cingulate during performance on an inhibitory task was associated with increased odds of the individual being rearrested within a 4-year period. In a community sample, Pardini et al. (2013) found that men with lower amygdala volume at age 26 exhibited higher levels of aggression and violence at a 3-year follow-up. These initial studies demonstrating that brain structure and function may add valuable information in the prediction of future offending raise a number of ethical questions, which will be discussed in the next section.

One problem with using brain imaging in crime prediction, however, is that there is no strong evidence that the brain abnormalities that are observed at one time point will persist in the future. Some evidence suggests that there is stability in activity in the prefrontal cortex in prisoners over a 4-year period (Anckarsater et al. 2007). However, there is also considerable evidence that the environment can change the brain. Research suggests that the environment plays a significant role in shaping how the brain develops and how it functions, even in adulthood, meaning that there is potential for change. While this makes crime prediction more difficult, an advantage is that we have the ability to make changes for the better. For example, studies have shown that cognitive and behaviorally based treatments can produce lasting changes in brain functioning in patients with other types of mental health problems. Felmingham et al. (2007) found that after 8 weekly sessions of exposure-based therapy, brain functioning was changed in the anterior cingulate and amygdala in patients with posttraumatic stress disorder (PTSD). Similarly, Paquette et al. (2003) found that abnormal activity in the dorsolateral prefrontal cortex and parahippocampal gyrus was reduced to the level of controls in a sample of participants with spider phobia. In contrast to the idea that antisocial behavior may be "hard-wired" in the brain, these studies suggest that we can make potentially long-lasting changes in brain functioning through various forms of treatment. Future research examining the stability of structural and functional brain imaging findings in individuals will be helpful in determining how much weight to give this type of evidence, particularly in cases in which the imaging is conducted well after the crime has been committed.

Brain imaging may also be particularly useful in identifying subgroups of antisocial individuals who may be more or less responsive to particular forms of treatment. Research on other disorders has found that brain imaging is useful in understanding why some individuals respond better to treatment. For example, approximately half of patients with PTSD do not respond to cognitive behavioral therapy, which is the treatment of choice for the disorder. Bryant et al. (2008) found that pretreatment levels of functioning in the amygdala and anterior cingulate, as measured by fMRI, predicted which patients would respond to treatment. Greater amygdala and anterior cingulate activity was associated with poorer improvement after treatment. Assessing levels of brain functioning similarly may help us to

identify individuals who are at risk for antisocial behavior, and provide information about whether a particular form of intervention may be helpful to that individual. As research progresses, we may be able to identify youth who are particularly susceptible to antisocial behavior, and provide intervention programs that are more effective at targeting the specific neurobiological deficits of the individual.

Ethical Issues

Suppose that, in the future, we are able to identify with 80 % certainty that a child or young adult will develop persistent, violent behavior, either by genetic tests, brain imaging, or other biological tests. Suppose further that we have treatment programs available that may reduce the risk by 30 % or more, and hence decrease the chances that innocent individuals will be victimized. Under such circumstances, would it ethically be permissible to mandate screening and intervention in early life? Who should decide whether or not an at-risk child should receive treatment? Also controversial is the issue of prenatal genetic screening, embryo selection, and reproductive liberty. According to Ronald Dworkin (1993), we have a right to procreative autonomy, which he defines as "a right [of individuals] to control their own role in procreation unless the state has compelling reason for denying them that control" (p. 148). Does our right to procreative autonomy include the right "to reproduce with the genes we choose and to which we have legitimate access" (Harris 1998)? Should parents be allowed to have a child that has a high genetic risk for violent, antisocial behavior? Should they have sole decision-making authority whether or not to have the child?

John Harris (1998) asks us to imagine the following: We have six pre-implantation embryos awaiting transfer, and genetic screening reveals that three of these embryos have genetic diseases and three are normal. Which three embryos should be implanted? Do we have moral reasons to prefer those without the genetic diseases? Let us change the scenario a bit and imagine that we have six pre-implantation embryos awaiting transfer and genetic screening reveals that three of the embryos have a genetic predisposition to violent, antisocial behavior. All else being equal, do we have moral reasons to prefer the implantation of the embryos without the genetic predisposition? What if there was only one viable pre-implantation embryo and genetic screening revealed a predisposition to violent, antisocial behavior? Imagine that we have the technology to safely alter a genetic predisposition to violence by prenatally manipulating the genetic variant(s) that contribute to this predisposition. Do we have moral reasons to genetically manipulate the embryo in question? Although these normative questions are obviously not on the agenda at present, they might become more relevant in the future if scientific progress in the field of genomic preventive medicine continues to grow.

At present, early screening and intervention may benefit some individuals at risk of developing a particular disease, but carries a substantial risk of increasing anxiety and stigma, and falling prey to unnecessary interventions. As mentioned, not all individuals who exhibit an increased biological risk for a specific disorder

will develop that disorder. Furthermore, the environment interacts with biological (including genetic) factors, and therefore should be fully considered. Pressing ethical dilemmas that we will be faced with when thinking about early screening for risk factors related to the development of mental disorders (e.g., genetic and biological predictors for violent, antisocial behavior) are related to: (1) the efficacy, cost-effectiveness, and likely "false alarm" rate of population-based screening strategies, (2) anxiety and stigma, (3) informed consent and the obligations between parents and children.

1. From a public health ethics perspective, population-wide screening of individuals (genetic or otherwise) is only justifiable if an efficacious and cost-effective intervention exists to prevent the development of the disorder in individuals who are identified as at-risk. However, even if efficacious interventions are available, we do not know whether screening and early intervention will be more cost-effective than treating those who actually have the disease or display disease symptoms. Moreover, it is unclear whether information about genetic risk is sufficient to motivate behavior changes and whether this information will motivate individuals enough to seek and continue treatment. It is possible that information about genetic or biological risk could undermine an individual's confidence in his/her ability to change his/her behavior for the better, and may therefore contribute to deviant behavior rather than preventing it. Alternatively, such knowledge combined with effective treatments to ameliorate biological risk factors could motivate antisocial individuals to seek treatment.

   In general, public health professionals have raised worries that population-wide genomic screening may draw our attention away from *more* effective population-based prevention strategies (e.g., prenatal and/or school-based nutrition programs, programs against child abuse and maltreatment, programs aimed at socioeconomic risk factors, etc.) that aim at lowering the risk for the entire population and not merely for a normatively defined at-risk group. When do we consider an individual to be at-risk, or to have a high versus low risk? The answer to this question involves normative judgments concerning health versus ill-health. Population-wide predictive screening and intervention strategies will involve false negatives, leaving out individuals in need of treatment, and false positives, leading to unnecessary interventions that may be considered harmful to the individual in question (Holm 2007). Interventions based upon population-based screening should not be a substitute for the implementation of policies that reduce exposure to common risk factors in the entire population.

2. Stigma reduces an individual to someone who is "tainted" and should be "avoided." Stigma can have many negative consequences by limiting access to material resources and opportunities and lowering psychological well-being. Through a process of social exclusion, stigma often aggravates diseases by discouraging individuals to seek treatment and by worsening treatment outcomes for those who are in treatment. Stigma can have long-term detrimental effects on the self-esteem and self-worth of stigmatized individuals and has been described as an assault on human dignity (Bayer 2008; Spriggs et al. 2008).

Should the harm that is caused by stigmatization be avoided at all cost? Do we have strong moral reasons to prioritize the potential harm that is caused by stigmatization over the potential benefits that may result from screening and effective interventions? Although stigmatization has the potential to significantly impact an individual's human dignity, it may be argued that the primacy of non-maleficence ("do no harm") is not absolute (Shickle and Chadwick 1994). According to Shickle and Chadwick (1994), there must be room for a trade-off between the harm that results from screening and the harm that is brought about by a failure to screen. However, while we may have legitimate reasons to opt for screening (preventing harm), we may also have legitimate reasons ("do no harm," e.g., stigma) to refrain from screening. Although we must acknowledge responsibility for the harm that is caused by a failure to screen (and thus failure to prevent), we should not implement every screening program that could conceivably prevent harm. Peter Singer (1979) proposes the following test: "If we can prevent something bad without sacrificing anything of comparable moral significance, we ought to do it" (169).

Spriggs et al. (2008) argue that a greater justification for screening children is needed for disorders that carry a greater risk of stigmatization. The higher the genetic determination of a particular disorder and the fewer the modifiable genetic determinants, the higher is the risk of stigmatization. In those cases, stigmatization is linked to mistaken neuro-essentialist beliefs that reduce an individual to his/her genetic or biological makeup and equate genetic or biological risk factors with "un-changeability" or "un-treatability." At the same time, Spriggs et al. (2008) predict that screening and intervention for mental disorders in early life is most likely to be of use for mental disorders with a high genetic determination. Indeed, screening and early intervention is unlikely to be of great value in disorders with a low genetic determination due to the unreliability of future disease risk. Based upon a cost-benefit analysis of genetic testing and an overall assessment of the reasons for and against genetic testing, Spriggs et al. (2008) argue that early screening for genetic (or biological) risk for mental disorders is not warranted unless there is a family history of mental disease, and unless efficacious, cost-effective, low-risk interventions exist to preventively reduce the risk. The authors do not make a difference between disorders that may involve violent, aggressive behavior toward others, such as antisocial personality disorder, and disorders that mainly involve self-harm. If effective treatment programs are available, could screening for violent, antisocial predictive factors in early life be warranted for children without a (known) family history? Do the potential benefits in terms of public safety outweigh the potential risks in terms of stigmatization and unnecessary interventions?

3. Imagine that a child, without ever having committed a violent crime, has been identified as at-risk for violent, antisocial behavior based upon genetic or biological screening and imagine further that treatment programs exist that may reduce this risk substantially. Who should decide if the child enters the treatment program? Should the parents have sole decision-making authority or should the child be involved in the decision-making process? "Child

protectionism" is the view that children, although they may have rights, are cognitively and emotionally incapable of deciding for themselves and, hence, of exercising their rights. Therefore, either their parents or legal guardians, in combination with professionals or legal authorities, should decide for them based on their current and future best interests. Child protectionists argue that too much weight has been placed on children's autonomy, and that this might be detrimental for children rather than empowering (Ross 1998). In contrast, "child liberationists" argue that children's rights should be respected and that children's views should be given due weight in accordance with their age and maturity. Lynn Hagger (2009) argues that parents have the duty to gradually diminish their proxy decision-making and allow their maturing children to make their own choices. By providing opportunities to choose for themselves, children can develop and learn the necessary skills to become competent adults. A shared decision-making model may be preferred because (1) this creates the kind of environment in which the child's developing autonomy is respected and the child's decision-making skills are nurtured, and because (2) shared decision-making has been found to result in better treatment outcomes and coping behavior (Focquaert 2011). As is the case with most interventions targeting behavior change, successful treatment will depend to a large degree on the willingness of the individual in question to undergo treatment. It is therefore of the utmost importance that the child is involved in the decision-making process and, preferentially, that a *shared* decision-making process can be established where the parent or legal guardian gives his/her informed consent and the child his/her assent.

Conclusions and Future Directions

Children have the physical, cognitive, and emotional means of being physically aggressive toward others by 1 year of age. Individual differences in the frequency and severity of this aggression can be observed shortly thereafter (Tremblay 2008). Unsurprisingly, there are biological differences that can be observed in children at very young ages, and some of these differences have been linked to increased risk for antisocial behavior. However, it is unlikely that genetic and neurobiological information will ever be precise enough to allow us to predict with very high probability that an individual will commit a specific act. Thus, concerns that biological information may eventually be used to predict crime before it occurs are premature.

A more likely scenario is that biological information may be used to identify which individuals are at somewhat greater *risk* for traits associated with criminal behavior. As discussed, there are a number of ethical considerations related to early screening and intervention that arise, including the substantial risk of increasing anxiety and stigma, and the issue of whether interventions should be mandatory. It is argued that a shared decision-making process involving both the parent and the child may produce the best outcomes.

One of the most difficult neuroethical challenges is finding the sensitive balance between protecting society and protecting our individual civil rights. With these issues in mind, it is suggested that biological research on criminal behavior should be viewed as part of the solution rather than part of the problem. Understanding the biological factors that influence criminal behavior puts us one step closer to understanding how this behavior develops, and will help us to create more targeted and sophisticated methods for prevention and intervention, which is the ultimate goal. These interventions often have benefits that extend beyond the goal of preventing antisocial behavior, and include improvements in school performance, social adjustment, and reduced risk of substance abuse and other mental health problems. By sensibly and cautiously integrating genetic and neuroscience findings with public policy, future crime and violence can be better prevented.

Mind, Brain, and Education: A Discussion of Practical, Conceptual, and Ethical Issues

108

Daniel Ansari

Contents

Abstract

Recent years have seen a tremendous growth in efforts to connect rapidly growing insights into how the brain learns to the field of education. Different names have been given to such efforts, including "Educational Neuroscience" and "Mind, Brain, and Education." The aim of this chapter is to discuss these recent efforts and to provide an overview of the conceptual, practical, and ethical challenges faced by these novel, transdisciplinary efforts. To do so, the chapter begins with an overview of some examples of recent research efforts to connect research on Mind, Brain, and Education (MBE). To do so, the chapter begins with an overview of some examples of recent research in the emerging field of Mind, Brain and Education. Specifically, the chapter reviews evidence from the study of the neurocognitive processes of typical and atypical reading development in an effort to illustrate the merit of MBE. This is followed by a discussion of the conceptual and practical challenges that MBE needs to consider, such as the level at which evidence from the study of neurocognitive processes can influence education and how neuroscientists and educators can play complementary roles in the

construction of the field. Against this background, the chapter considers ethical challenges, including the need to effectively and accurately communicate evidence, to carefully consider the commercialization of neuroscience, including the use of brain stimulation, to enhance cognitive functions and for classroom application.

Introduction

Recent decades of neuroscience research have witnessed an unprecedented growth in our understanding of the neural mechanisms that subserve human learning. Significant advances in our understanding of the neuronal machinery that allows humans to acquire complex skills such as reading, writing, mathematics, and problem solving have been made. Furthermore, our understanding of brain development and how experience changes brain function and structure has grown tremendously (Johnson 2001; Lenroot and Giedd 2006; Munakata et al. 2004). We are learning not only how the brain comes to process the content of the most classical domains of education, such as numeracy and literacy, but insights into the brain mechanisms underlying motivation, attention, and working memory are constraining our understanding and modelling of how children acquire new skills that are essential to their success in society.

Against the background of these advances in basic research, there have been growing calls to apply knowledge from neuroscience to education. On the surface, it is a “no-brainer” that neuroscience should be capable of informing education. Without our brains, we cannot learn and therefore understanding the machinery (the brain) that underpins the ability of children and adults to learn in the context of educational settings should have implications for how to improve educational environments and pedagogy. A key concept here is “neuronal plasticity” – the ability of the brain to change as a function of experience. Early neurophysiological studies revealed that sensory deprivation or enrichment changes the brains of animals, showing that experience shapes the brain (Buonomano and Merzenich 1998). Today, we can study the effects of complex environmental and experiential differences, such as cross-cultural variability, on brain structure and function (Ansari 2012). Mounting research suggests that the brain is more plastic than we originally thought (though within constraints) and that our brains continue to be capable of functional and structural change (plasticity) in adulthood, which has potential implications for life-long learning, a topic of much interest in many aging Western societies (May 2011).

Plasticity is key to education. Teachers are the orchestrators of their students’ neuronal plasticity during classroom time. In order for knowledge to be acquired, the brain has to encode information, which involves changes in the connectivity between nerve cells (i.e., synaptic plasticity). The brain is not a static organ, but instead dynamically adapts to the environment. Education is a process of inducing brain plasticity through instruction in a social context. When children learn, for example, to read (for a greater discussion of this topic, see below), their brain changes from them seeing letters on the page as meaningless characters to the point at which they read with a flashlight at night and use these previously meaningless characters to follow stories and create meanings in their minds.

Notwithstanding strong critics (Bruer 1997), over the past 15 years or so, the enthusiasm for a new science of learning and education that combines insights from cognitive science, neuroscience, and psychology has grown exponentially. Terms such as "Neuroeducation," "Educational Neuroscience," and "Mind, Brain, and Education" have been used to describe these efforts. The author of the present chapter prefers the term "Mind, Brain, and Education" (henceforth MBE) because it reflects the mutual and interactive influence of research from cognitive psychology, neuroscience, and educational research. New organizations such as the International Mind, Brain and Education Society (IMBES; www.imbes.org) and journals (e.g., "Trends in Neuroscience and Education" and "Mind, Brain and Education") have been launched to attract research and theory that lies at the intersections between neuroscience, education, cognitive science, and psychology." Interest in such new directions has extended beyond the realm of academia. Organizations such as the Organization for Economic Cooperation and Development (OECD) have convened expert groups to examine the relationship between Mind, Brain, and Education in an effort to find ways to improve education in OECD membership countries across the globe (OECD 2002). In addition, new graduate programs are being launched in many departments, the first of which was the Master's in Mind, Brain and Education at the Harvard Graduate School of Education founded by Dr. Kurt Fischer (http://www.gse.harvard.edu/academics/masters/mbe/).

As can be seen from the above, the field of MBE is growing rapidly. As with any new field, there are many conceptual, practical, and ethical issues to consider in order to facilitate the successful growth of the field. The aim of this chapter is to provide a critical reflection on and discussion of the potential of Mind, Brain, and Education. The chapter will commence with a discussion of examples from neuroscience research that are having implications for education and to illustrate some of the findings from neuroscientific research that are fueling the enthusiasm for Mind, Brain, and Education. The review of these findings will also consider how evidence from cognitive neuroscience might impact education now and in the future. The chapter will then turn to conceptual and practical challenges that are faced by this new, translational field. Against the background of having considered what MBE research looks like and what challenges face the field, the chapter will discuss the ethical challenges that the emerging field of Mind, Brain, and Education is and will be confronted with.

Examples of Success in "Mind, Brain, and Education"

The aim of the following section is to provide the reader with some examples of recent interdisciplinary research that demonstrates the potential of the emerging field of Mind, Brain, and Education. This review does not aim to be comprehensive, but simply to illustrate through a few examples the potential significance of research that bridges the gap between cognitive neuroscience and education.

Perhaps, the best example of how neuroscience research is shaping education comes from research in the domain of reading and the breakdown of reading abilities (i.e., Developmental Dyslexia). Noninvasive brain imaging methods such as functional Magnetic Resonance Imaging (fMRI) and Event-Related Potentials (ERPs) have enabled researchers to map out the brain regions involved in reading and to image the time course of neural activity associated with the process of reading. Through the use of such methods, it has become possible not only to study which brain regions are involved during reading, but how these change over the course of learning and development as well as what differences exist between the brain structure of typical readers and those with Developmental Dyslexia (for reviews, see: Gabrieli (2009); Schlaggar and McCandliss (2007)). The aim here is not to provide an exhaustive review of these studies but to highlight some findings that show how neuroscience can be used to constrain educational problems and inform educational practice. One area in which neuroscience is making great strides is in the prediction of reading success and failure. For example, several studies using ERPs to record the brain responses of neonates and infants, have revealed that infants brain responses to sounds predict individual differences in reading years later (Guttorm et al. 2001, 2010; Molfese 2000; Pihko et al. 1999). These are powerful data for a number of reasons. First of all, they reveal that the pre-reading brain of infants who will go on to experience difficulties in reading respond differently to those who will develop normal literacy skills. This draws attention to the early scaffolds of reading, resulting in many potential implications for early diagnosis and remediation. Secondly, these kinds of data are difficult to obtain with any other measure traditionally used in behavioral research with young infants and children, thereby demonstrating the added value of using neuroimaging methods.

In studies with older children using both structural and functional neuroimaging, it has been demonstrated that structural variables, such as brain volume and white matter integrity, as well as functional measures of brain activation during reading-related tasks (e.g., rhyming), predict significant variability in children's reading scores. One might argue that this is hardly surprising and that it is far more cost-effective to use traditional behavioral measures as predictor variables. However, Hoeft et al. demonstrated that the combined use of behavioral and neuroimaging measures as predictors of reading (specifically decoding skills) explains significantly more variance than either measure used in isolation (Hoeft et al. 2007). Thus, neuroimaging and behavioral measures each explain unique variance, which leads to overall better prediction of reading outcomes. These data speak against the notion that neuroimaging does nothing in addition to what can be gleaned from behavioral measures alone, but instead shows that such measures explain outcomes that cannot be captured by behavior alone.

In a more recent study, Hoeft et al. showed another powerful way in which neuroimaging measures can be used to predict educationally meaningful outcomes. The authors asked whether neuroimaging data could predict who will go on to show gains in reading performance. In addition to a large battery of behavioral tests of reading, writing, and IQ, structural and functional brain imaging data was acquired from children with and without Developmental

Dyslexia. The same children were tested again 2.5 years later. Behavioral data suggested that while some children with Developmental Dyslexia exhibited significant gains in reading abilities, another group of children demonstrated no change on behavioral tests of reading competencies. By using the behavioral and neuroimaging data acquired at the outset of the study to predict who ended up showing reading gains compared to children who did not, the authors were able to show that structural and functional neuroimaging measures were able to predict which children ended up exhibiting gains in their reading abilities. In striking contrast, none of the behavioral variables were able to statistically predict which children exhibited gains (Hoeft et al. 2011). These findings provide strong evidence for the possibility of "neuroprognosis" and also demonstrate that, in some cases, neuroimaging measures (both structural and functional) may be a more sensitive way in which to predict later outcomes (given that the behavioral data did not exhibit such predictive power). In addition to providing strong evidence to suggest that neuroimaging measures can be used to predict change in educationally relevant outcomes (e.g., gains in reading ability), Hoeft et al. found that individual differences in the structure and function of the right inferior frontal cortex were particularly predictive of such gains. This is an interesting finding, as reading is mostly associated with a left-lateralized network of brain activity and structure. However, there have been other studies suggesting that the right hemisphere plays an important role in response to intervention and may represent compensatory neural mechanisms (Temple et al. 2003). Thus, individuals who are better able to use these right-lateralized compensatory mechanisms may show greater gains in reading ability. This finding provides a significant constraint on our understanding of the mechanisms that drive individual differences in improvements in reading abilities. It is not as though we necessarily see the normalization of disrupted brain circuits, but instead it appears that the recruitment of regions not typically associated with reading is what is associated with the recovery of impaired reading skills. This is not only important from the point of view of understanding the mechanisms underlying the recovery of reading abilities, but it may also help to constrain how reading interventions are designed. In other words, future efforts may be directed at better understanding what mechanisms drive the recruitment of such compensatory neural processes and how these might be optimally harnessed. In this way, neuroimaging provides novel constraint on recovery of cognitive function and by revealing the mechanisms can guide future intervention programs.

Importantly, this is not an isolated case of "neuroprognosis." Very recently, Supekar et al. (2013) showed a similar result for the prediction of response to intervention in the domain of math learning. These researchers demonstrated that measures of hippocampal volumes as well as functional connectivity between the hippocampus and other brain regions were a significant predictor of individual differences in response to a structured intervention for children with math learning difficulties. Furthermore, convergent with the data from reading reviewed above, the behavioral data acquired prior to the intervention were not able to predict individual differences in the response to intervention. Thus, these data

provide convergent evidence for the potential power of neuroprognostics from two domains: reading and mathematics.

Another recent neuroscientific study of reading further illustrates the value added of neuroscience in addressing educational questions. One of the most hotly debated topic in special education is the use of so-called discrepancy criteria (Stanovic, 2005). Many researchers and practitioners define children as having specific difficulties in domains such as reading, writing, and arithmetic if they have below the normal range scores on the domain of interest but perform within the normal range on other tests of abilities. So, for example, according to the discrepancy criteria approach, a child with Developmental Dyslexia can only be defined as such if their reading abilities are both well below their general academic abilities and if their non-reading abilities are within the normal range. There have been many arguments against such stringent discrepancy criteria with researchers suggesting that children who have reading difficulties that are either discrepant or non-discrepant from their other intellectual and academic abilities have the same educational needs and are indeed indistinguishable from one another when it comes to measures of their reading ability (Fletcher et al. 1992). In a recent study, neuroimaging was used to constrain the question of whether children with and without a discrepancy between their reading and IQ scores showed different patterns of brain activation (Tanaka et al. 2001). The authors compared the brain activation of children with and without a reading-IQ discrepancy while they performed a reading-related task during functional neuroimaging (fMRI). Both univariate and multivariate analyses of the functional imaging data clearly demonstrated that both groups of children exhibited indistinguishable patterns of under activation (relative to non-impaired controls) of areas in the left hemisphere that are typically associated with successful reading. These findings show that the neurobiology underpinning reading does not differ between children with and without a reading-IQ discrepancy and therefore place a significant novel constraint on the special education debate surrounding the utility of using discrepancy based criteria to identify children with specific learning difficulties.

Beyond the domain of reading, there are many other examples in other educationally relevant areas that can be characterized as success stories in the emerging field of "Mind, Brain, and Education." For example, several studies, ranging from experiments with rats to functional neuroimaging studies with humans, have demonstrated the powerful effect that socioeconomic status and early experiences have on brain structure and function (Hackman et al. 2010). These data have revealed how early experiences and stress embed themselves into our biology and have long-term consequences for our health, well-being, and ability to learning. Without going into the details of the individual studies that demonstrate these powerful effects of early experience and socioeconomic status, these findings clearly have very important implications for education. They demonstrate the importance of early educational programs, especially in disadvantaged communities, in mitigating the profoundly negative effects of early, adverse experiences.

Conceptual and Practical Challenges

The above section provides a non-exhaustive discussion of some select examples (primarily from the study of the neurobiology of typical and atypical reading acquisition) of successful research in the emerging field of “Mind, Brain, and Education.” While such advances illustrate that there lies much promise in such transdisciplinary research, there are also many conceptual and practical challenges that lie in the path of such efforts. The aim of the following section is to discuss some of these challenges and potential ways of navigating such obstacles.

Whenever different fields of both inquiry and application meet one another, a need for a common language and set of expectations emerges. One expectation that is prevalent when neuroscience and education meet is that neuroscience will have a direct impact on classroom instruction (Ansari and Coch 2006). In other words, scientists generate evidence, communicate this evidence to educators who will then go on to apply it. This expectation will inevitably lead to disappointment, as results from research cannot be directly applied, but instead need to be gradually translated through an iterative process that needs to involve multiple bidirectional interactions between the research laboratory and the classroom and requires individuals who are well versed in both cognitive neuroscience and education to facilitate the process of translation (Ansari and Coch 2006; Varma et al. 2008).

Translation of evidence does not involve the presentation of recipes by researchers to educators, but must involve a collaborative effort that allows for the establishment of a common language and sets of expectations. In other words, to ensure successful transdisciplinary interactions between cognitive neuroscience and education, it is critical for expectations to be realistic and that a broader conceptualization of potential translations of insights from research into practice be adopted. Take the examples of studies, discussed above, revealing brain signals measured in neonates during language processing predict literacy impairments many years later. One may ask some of the following questions upon being presented with this evidence: what to do with this evidence in terms of practice? Does it mean that we can intervene very early in development or does it mean that the fate of children is determined from an early age onward and cannot be changed? If we can intervene, then how and when? What is the diagnostic utility of the event-related potential measurements for individual babies? Is it reliable enough to serve as a diagnostic tool? When considering these questions, it quite rapidly becomes apparent that research generates questions whose answers may lead to translation, but that the raw evidence often cannot be directly translated into practical applications. Evidence, whether from neuroscience or other scientific disciplines, is the beginning of a translational process.

The expectation that research will be directly translated into application also reflects another common assumption: insights from the research laboratory will invariably *change* education. Visions of entirely new classrooms come to mind that are “brain friendly” or a complete revolution in the way in which certain subjects are currently taught. While it is indeed possible that new evidence will lead to

changes in education, evidence can also play a critical role in affirming as well as speaking against what educators already do today and thereby strengthen certain approaches they adopt in their pedagogy every day. In this way, evidence may help to provide empirical grounding to certain educational approaches and techniques. In the above discussion of research on the neuroscience of dyslexia, powerful examples of how neuroscience can inform educational decision and help to arbitrate between different approaches was discussed.

The study by Tanaka et al. demonstrates that the neural correlates of reading impairments do not differ between dyslexics who were diagnosed using a reading-IQ discrepancy criteria and those who were not (who therefore showed impairments in reading and other cognitive functions). This confirms that discrepancy criteria used to diagnose children with developmental dyslexia do not appear to isolate a group of children who have qualitatively different neuronal deficits in reading from those who also have non-reading difficulties (Tanaka et al. 2011). This study therefore can be used to inform educational decision-making, in this case the method of diagnosing children with reading impairments. It does not change the way in which diagnoses are made, but instead provides critical information to guide decision-making. The use of evidence to confirm or disconfirm certain pedagogical choices is a powerful way by which evidence from the cognitive neuroscience laboratory can influence education and may indeed initially be the most realistic way in which education and cognitive neuroscience can be connected in the context of educational practice (Thomas 2013).

A similar role of neuroscientific evidence was recently highlighted by Laurence Steinberg in a discussion of the role that neuroscience has played in US supreme court decisions regarding the criminal culpability of adolescents (Steinberg 2013; see also Johnson & Giedd, this volume). What Steinberg argues is that neuroscience most likely had an influence on the legal decision-making not by revealing something completely new that no other previous evidence, such as behavioral evidence, had shown, but by confirming common sense, intuition, and evidence from behavioral evidence. In other words, neuroscientific evidence played an important supportive role in the process of legal decision-making.

One might argue that if the role of scientific evidence, such as data from cognitive neuroscience, plays only a supportive role, then one might as well ignore it. This argument, however, ignores the fact that confirmation of one set of opinions or intuitions is often accompanied by the rejection of alternative approaches where there either does not exist evidence to support their efficacy or evidence that demonstrate that such approaches are inefficacious. In this way, evidence provides a means by which to inform education. Rather than basing educational decisions on opinions and intuitions, a culture of evidence-based education uses evidence to make informed decisions.

It follows from the above discussion that, if teacher education programs were to systematically train teachers in the evaluation of empirical knowledge during preservice training, then such individuals would be better equipped to use evidence to inform their pedagogical decision-making. This would allow teachers to become

critical consumers of empirical evidence from a range of field of inquiry relevant to education, including but not restricted to evidence from cognitive psychology and neuroscience, and to seek out evidence to both confirm and reject particular educational approaches (Ansari 2005). Training teachers and other educational professionals in the language of science, how evidence is generated and evaluated, may hold the key to effective processes of translation. In the same way, cognitive neuroscientists generating evidence, which they hope will inform education, should become versed in pedagogy and approaches in educational practice and research. This will lay the foundation for translation that is supported by individuals from a multitude of backgrounds to ensue.

Ethical Challenges

Having considered some, but certainly not all, of the practical and conceptual challenges faced by the field of Mind, Brain, and Education, the present discussion now turns to the ethical challenges that this field of inquiry has encountered as well as those that might lie in its future paths. This discussion will not consider ethical challenges associated with the use of neuroimaging methods to study the developing brain (for an excellent discussion of such challenges, see: Coch 2007). Instead the present section will consider broad ethical challenges that lie at the conceptual, rather than the methodological, level of Mind, Brain, and Education as a new field of inquiry.

Recent years have seen an impressive increase in the public's awareness and interest in neuroscience. Popular magazines are full of articles about the brain, and neuroscience is enjoying an unprecedented amount of public attention. While such attention is broadly welcome (at least from the vantage point of neuroscientists), it does also pose some significant challenges that require the attention of neuroscientists. One of these is the creating of a knowledge hierarchy. Specifically, because of the great attention paid to neuroscience, its informational merit, relative to other sources of evidence, may be judged too highly. As discussed above, the role of neuroscience is most frequently a complementary one. In other words, neuroscientific evidence can inform other areas, such as education, in conjunction with insights from other disciplines, such as the behavioral sciences. A set of recent studies have demonstrated that the great value assigned to neuroscientific evidence may not always lead to good conclusions about that evidence. One of these examined the influence of brain images on how individuals evaluate scientific evidence. Noninvasive imaging methods, such as functional Magnetic Resonance Imaging (fMRI), generate aesthetically pleasing images of brain "activation." These images, of course, are not a direct representation of "activity" but rather represent color-coded statistical maps showing the probability of the "activation" (which in turn is represented by changes in blood flow that are thought to correlated with neuronal activity) in certain brain regions. These images provide powerful illustrations of data, but it turns out that their presence can also have a significantly negative influence on the way in which non-experts evaluate neuroscientific evidence (Weisberg et al. 2008). Specifically, Weisberg et al. presented both naïve

adults, students in a neuroscience course and neuroscience experts with explanations of psychological phenomena. These explanations were varied in two ways: (1) They were either good explanations or invalid explanations. (2) They were either paired with or without neuroscientific evidence; however, this evidence was completely irrelevant to the logic of both good and bad explanations. The investigators found that this irrelevant neuroscientific evidence influenced the way in which the group of naïve participants and the neuroscience students judged the explanations. Specifically, these participants were more satisfied with explanations that were paired with irrelevant neuroscientific evidence and, perhaps most alarmingly, they were less likely to recognize the bad explanations (i.e., found them more satisfying than bad explanations without irrelevant neuroscientific data contained within the explanation) when these were paired with irrelevant neuroscientific evidence. In other words, the presence of neuroscientific evidence appeared to make non-experts think more highly of bad explanations of scientific phenomena.

The study by Weisberg et al. is a powerful explanation of how the current "hype" around neuroscience could lead to biases in the way in which individuals evaluate the validity of scientific evidence. However, it is very important to consider that the study by Weisberg and colleagues and related investigations of the effect of brain images on scientific evaluations (McCabe and Castel 2008) have recently not been replicated (Michael et al. 2013) in large-scale studies and therefore, it is unclear how reliable these effects are and how specific they are to brain images, as opposed to other stimuli that could bias the judgment of scientific data (Farah and Hook 2013).

Regardless of whether the results are reliable and are specific to neuroscience, there are some general ethical implications for researchers in the field of MBE that go beyond the particulars of this research. Specifically, researchers in this emerging field of inquiry need to recognize that their understanding of the strengths and limitations of neuroscientific evidence is not necessarily at the same level of individuals who are not trained in neuroscience and therefore the way in which evidence is communicated becomes a critical ethical issue for researchers in MBE, particularly those who are generating neuroscientific evidence. Researchers in MBE must be aware of how their research results may be perceived by non-experts, such as teachers, and must therefore ensure that their findings are communicated in ways to avoid misunderstandings and the inappropriate use of the evidence. Researchers must think carefully about how they talk not only about the evidence they have generated but also about its implications for the classroom and to avoid overstating the potential for direct application. For example, teachers may not be aware that neuroscientific data is often based on averages and thus, a given finding may not be representative of every student or that must studies in cognitive neuroscience are conducted with adults participants and that the data may not be readily generalizable to children. Therefore, neuroscientists need training in how to communicate to and engage with the public in ways that are ethical and thereby avoid the creation of misconceptions (Illes et al. 2010).

Effective communication and engagement is especially important when it comes to sharing neuroscientific evidence with educators. Many teachers are extremely enthusiastic about neuroscience and seek out opportunities to learn more about

neuroscience (Hook and Farah 2012). This enthusiasm represents a great opportunity for the field of Mind, Brain, and Education to grow and for dialogue between neuroscience and education to ensue. Without educators and "buy-in" from educators, the transdisciplinary field of MBE cannot succeed. However, such dialogue must be effective and avoid scenarios that lead teachers to construct misconceptions about neuroscience, or so-called neuromyths. Some so-called facts (neuromyths) about the brain, such as the idea that we only use 10 % of our brains or that some individuals are "left-brained" while others are "right-brained," appear to be very persistent among teachers (OECD 2002).

In a recent study of primary and secondary teachers in the Netherlands, it was found that around half of them believed neuromyths (Dekker et al. 2012). Moreover, and perhaps more alarming, the authors found that those teachers who were enthusiastic about neuroscience and read more popular science magazines were also those who were more likely to believe neuromyths. These data demonstrate the importance of providing teachers with better tools to evaluate scientific evidence in order to avoid misconceptions about neuroscientific (and other empirical) evidence that could be informative in terms of their pedagogy (Dubinsky 2010). Furthermore, it is important that researchers think carefully about how this evidence is going to be presented to teachers. The finding that those who read more popular science magazines were also more likely to believe in neuromyths provides a stark illustration that information itself is clearly not enough, but that the quality of that information and how it is delivered matters. It is likely that such training might be most efficient at the preservice level so that teachers enter their profession not only seeking evidence-based approaches to their pedagogy but also being capable of carefully evaluating evidence.

The ethical challenge, for both neuroscientists and teacher education institutions, of addressing the prevalence and proliferation of neuromyths among educators, is further exacerbated by the commercialization of so-called brain-based programs. These programs are often advertised as being based on neuroscientific data, though a closer examination often reveals that such data are, at best, tangentially related to the commercial programs that are being advertised. Furthermore, the majority of such programs have not been evaluated in adequately controlled trials and therefore, it is unknown to what extent they will be efficacious.

In a large-scale evaluation of computerized programs that purport to train certain brain functions, it was recently found that while training on such tasks improved task performance, there was no evidence of transfer of the trained abilities to other tasks, even if they involved very closely related neurocognitive functions (Owen et al. 2010). Thus, the promised effects of the "brain training" programs investigated did not hold. Furthermore, in some cases, the empirical evaluation of such programs reveals that they can actually lead to decrements in certain neurocognitive functions rather than improvements. In a study evaluating the effect of babies watching special "educational" programs on the infants language development, Zimmerman and colleagues found that greater consumption of such videos was associated with decrements rather than improvements in language development, as measured by a parental questionnaire regarding the child's communicative abilities (Zimmerman et al. 2007). This is, of course, not to say that all so-called brain

training programs will be either inefficacious or harmful, but these two studies demonstrate the importance of grounding such applications in empirical research and making sure that educators demand such evidence before investing financial and pedagogical resources into their application.

Educators who are not trained in evaluating products and asking questions about the evidence base behind them, but who are, at the same time, highly enthusiastic about neuroscience may buy into such programs without reservations. To avoid the proliferation of such “brain-based” approaches in classrooms, it is important that individuals, such as administrators and classroom teachers who have the responsibility of choosing such programs, are trained in how to judge the efficacy of an educational program as well as the evidence base (or lack thereof) of any program that is being offered to them. The same applies to books written on “brain-based” education. If neuroscientists and teacher educators do not take action to prevent the spread of empirically unsupported programs and books, then this could lead to the further proliferation of neuromyths and the application of untested programs that may have no effect at all or, even worse, detrimental effects on neurocognitive functions. The field of MBE now needs an infrastructure for such training and ethical information sharing to take place. Training teachers and educational decision makers is going to be insufficient in preventing the proliferation of “brain-based” programs that have no supporting evidence. More and more such programs will flood the market as interest in neuroscience and its application to education increases. Neuroscientists and educators should therefore work together with politicians, funding agencies, and regulators to come up with guidelines. Eventually, given the critical role that education plays in society, there should be regulatory organizations, similar to those that exist to regulate medical products.

Beyond considering neuroscientific evidence that has implications for education by virtue of showing how learning in certain domains affects brain structure and function, there exists a growing body of research that explores attempts to stimulate the brain in order to enhance cognitive functions (e.g., Cohen Kadosh et al. 2010; Hauser et al. 2013). Such studies are suggesting that the application of weak electrical current to the brain via scalp electrodes can lead to enhancements of cognitive functions through the induction of plastic changes in the neuronal architectures supporting these functions. These studies have received widespread attention in the media and it is foreseeable that commercialization of such approaches will take place shortly, if it is not already underway. One could imagine then, that it will not be too long before schools are offered packaged brain stimulators for their students that are to be applied during instruction to improve learning. This therefore raises a whole host of ethical considerations related to the potential, undesired, and uncontrollable side effects of such stimulation.

In this context, it is important to consider that while the data suggesting that methods such as Transcranial Direct Current Stimulation (TDCS) are intriguing, the existing studies are exclusively conducted with comparatively small samples of adult participants, therefore making their generalizability to samples of children impossible to estimate. Children’s brains are developing and cannot be readily compared with those of adults. Therefore, the response of children’s brains to

stimulation may be quite different from what is currently being observed in adults. Moreover, though many study show improvements on behavioral measures following brain stimulation during learning, there also exists evidence to suggest that such stimulation can also have negative effects on cognitive processes (Iuculano and Cohen Kadosh 2013). Thus, it is clear that brain stimulation does not only affect the neurocognitive functions it is aiming to target but leads to side effects, the extent and magnitude of which is unknown. Generally, brain stimulation studies are very much in their infancy and little is known about the mechanisms through which brain stimulation exerts its effects on learning. Given this, researchers have an ethical responsibility to communicate about the potential of such methods to be applied in the classroom with caution. It is likely that such approaches and similar ones that try to modulate neurocognitive functions that are relevant to educational processes via stimulation or pharmacology are going to rapidly increase over the coming years and thus this will be a major frontier of neuroethics for MBE.

On a broader level, it is the contention of this author that MBE must keep in mind that education is a deeply cultural activity. As such, education is not a fixed entity. Education varies across historical time, contexts, and cultures. The priorities of what children should be learning changes with the general shifts in our societies and cultures. It is brain plasticity that allows for these rapid adaptations to changing sociocultural demands and contexts.

Often when discussing the role of neuroscience in education, the metaphor of a muscle is used. Specifically it is argued that the brain is like a muscle that needs to be exercised and that therefore education is a form of exercising your brain. In the opinion of the present author, this metaphor is overly simplistic and its implications may be misleading. While there is a range of ways in which you can exercise the muscles in your body, it does not by any stretch of the imagination resemble the diversity of how and what humans learn. Learning and education are not simply the acts of exercising a muscle in a particular way that can be replicated across cultures and contexts.

Though neuroscience has great potential to provide information that could improve education and help us decide which educational approaches are most optimal (through systematic, evidence-based evaluation), it will never be able to inform us as to what we should be teaching our children. Neuroscience is and should be agnostic as to the specific goals of education. This will remain the purview and responsibility of societies. Therefore, the discussion around issues in MBE and the neuroethics of it should consider that efforts to bring neuroscience to bear on educational problems do not lead to normalization of education across time and context and a fixed view of what education means and what children should and should not learn.

Summary and Conclusions

Evidence from neuroscience is increasingly discussed in the context of education. How can we use our growing insights into the mechanisms by which the brain learns across domains to improve education? This is a hotly debated question today.

On the one hand, there is much to be enthusiastic about. The study of education is in many ways the study of brain plasticity. If our brains were unable to change in response to experience, education would not be possible. Every month, new studies are published that show how the brain changes as a function of learning across different domains, such as reading and mathematics. On the other hand, while the evidence base is steadily growing, efforts to translate such evidence into educational practice face significant conceptual, practical, and ethical challenges.

There is a need to move beyond models of translation that focus on the direct translation of neuroscience laboratory research to the classroom and instead engage in a more iterative process of translation that involves neuroscientists, educational researchers, and practitioners. Furthermore, beyond changing education, evidence from neuroscience *in conjunction* with evidence from other domains has an important role to play in supporting what is already being implemented in education (thereby lending evidence to approaches that have previously not been evidence-based) and in using evidence to inform educational decision-making. The role of empowering educational professionals and decision makers through giving them tools to be critical consumers of evidence is discussed as both a conceptual and ethical challenge. Neuroscientists need to assume greater responsibility in ensuring that the information they generate is interpreted correctly and must guard against the proliferation of neuromyths, premature commercialization, and the use of neuroscientific approaches to enhance neurocognitive functions that have not been systematically tested in pediatric populations and for which side effects are currently understudied.

Finally, while there is much reason to be enthusiastic about the emergence of MBE, it is important that society continues to discuss the direction of education independently of neuroscientific evidence. While evidence from neuroscience can inform which approaches work and why and perhaps help to optimize them, education and educational priorities remain deeply cultural activities.

J. Clausen, N. Levy (eds.), *Handbook of Neuroethics*,
DOI 10.1007/978-94-007-4707-4_148,

about where to draw the line between childhood and adulthood for policy purposes has highlighted a number of complex neuroethical issues including: balancing responsibility and autonomy, the strengths and frailties of human competence, and decision making in the era of neuroimaging. In this chapter, two public policy issues: Informed consent and legal culpability are used to illustrate the emerging neuroethical challenges and opportunities involved in using neuroscience to inform child and adolescent policy.

This chapter begins with an overview of historical attempts to use biological benchmarks of adult maturity. This historical perspective is followed by an introduction to the neuroethical issues involved in informed consent and legal culpability for adolescents, and the brain and behavioral science that has been brought to bear on these policy questions. The focus of this scientific review is the development and deployment of the cognitive capacities that are the foundation of maturity of judgment during late childhood and adolescence: self-control, inhibition, emotion regulation, and vulnerability to peer influence. Finally, the opportunities and potential pitfalls involved in using brain science to inform child and adolescent policy are considered.

Introduction

In the last 25 years, magnetic resonance imaging (MRI) technology has fundamentally changed the way the development of the human brain is conceptualized. It is now well established that brain structures and the communication among them change throughout childhood and adolescence, and indeed, across the life course (Giedd et al. 1999; Sowell et al. 1999, 2001). These new understandings have prompted re-examination of long-held ideas about what maturity means, both biologically and behaviorally. Particularly salient for health and legal policy is establishing the point in cognitive and socio-emotional development at which children become adults. Two areas of public policy have brought the developmental neuroscience of childhood and adolescence into sharp focus: informed consent and legal culpability. These policy issues have exposed inconsistencies among sociological, political, and biological definitions of maturity, and have shaped the public conversation about where to draw the line between childhood and adulthood.

This chapter begins with an overview of historical attempts to use biological benchmarks of adult maturity. This historical perspective is followed by an introduction to the neuroethical issues involved in informed consent and legal culpability for adolescents, and the brain and behavioral science that has been brought to bear on these policy questions. The focus of the scientific review is the development and deployment of self-control, inhibition, emotional regulation, and peer influence during late childhood and adolescence. Finally, the opportunities and potential pitfalls involved in using brain science to inform child and adolescent policy are considered.

Defining Maturity

The line between childhood and adulthood, while indistinct from a developmental point of view, is clear for the purposes of informed consent and legal culpability. Adulthood is the point at which individuals are considered competent both to make autonomous choices about their well-being, and they are held legally responsible for those choices. Throughout history, a number of biological benchmarks have been used to codify the skills needed to successfully participate in the tasks of adulthood. For example, in thirteenth century feudal England, the age of majority (i.e., legal recognition of adulthood) was raised from 15 to 21, citing the physical strength needed to bear the increasing heft of metal protective armor and the skill required to fight on horseback (James 1960). Absent such tangible physical requirements, contemporary legal definitions of adulthood are arguably developmentally arbitrary, and certainly less consistent. The age of consent for marriage has varied historically and currently varies widely by country (from puberty to age 21) and within the United States. For example, in New Hampshire, the marriageable age with parental consent is 13 for females and 14 for males, and 18 for both sexes without parental consent. In Nebraska, both males and females must be at least 17 with parental consent and 19 without parental consent. Age of consent for sex is now between 16 and 18 in all US states, but in 1880 ranged from ages 7 to 12, with most states setting the minimum age at 10 (Robertson 2008). Minimum ages for involvement in the political process are also nonuniform. Although the voting age in the USA has been 18 since 1972, the minimum age to hold office varies from 18 for mayor, 21 for governor, 25 for Governor or Representative, 30 for Senate, and 35 for President. Age of conscription is 18, drinking alcohol 21, tobacco 18, purchasing a rifle or shotgun 18, and a handgun 21. The range of these ages is at odds with a more fundamental biological notion of a distinct maturation level at which a person can make sound decisions on his or her behalf and participate independently in society.

Perhaps because they recognize the potential utility of a more developmentally informed approach, policy makers and judges have called on developmental scientists to weigh in on when adolescents can be expected to think and behave like adults. In this chapter, the policy issues of consent and culpability are considered to illustrate how new understandings of the “teen brain” have informed ethical questions about autonomy and justice at the threshold of adulthood.

Legal and Developmental Issues in Consent and Culpability

Informed Consent

Informed consent is a core principle of bioethics. The ethical precept of respect for persons dictates that cognitively competent adults should be free to make their own choices about their health and health care. In the USA, before age 18, consent to medical treatment generally requires parental consent; minors are assumed to be incompetent under the law. Instead, parents are charged with representing and

protecting the best interests of their children (Thomas and O'Kane 1998). The law does, however, recognize that adolescents stand, for the purposes of maturity, somewhere between adults and children (Ford et al. 2004). A "mature minor" is allowed to provide informed consent if he or she demonstrates "sufficient maturity to understand and appreciate the benefits and risks of the proposed medical treatment" (Derish and Heuvel 2000, p. 115). (It is worth noting that this is a *cognitive* definition of maturity). While current laws vary by jurisdiction, minors may consent to a subset of medical services without parental consent/notification. These services include: testing for sexually transmitted infections, contraception, prenatal care, drug and alcohol treatment, mental health services, and abortions (American College of Obstetricians and Gynecologists 2009). In addition to recognizing the adolescent's increasing autonomy, there is a public interest in removing barriers to contraception or treatment. Adolescents have among the highest rates of foregone health care, and concerns about privacy from parents have been shown to be a significant deterrent to seeking care (Ford et al. 1999, 2004).

In 1990, before longitudinal neuroimaging research demonstrated protracted development of the child and adolescent brain, the US Supreme Court grappled with the issue of adolescent maturity of judgment for the purposes of making autonomous health care decisions. In *Hodgson vs. Minnesota*, physician Hodgson contested the State of Minnesota's law that required both parents be notified before a minor could receive an abortion (United States Supreme Court 1990). Ultimately, the Court decided that only one parent must be notified, and established a judicial bypass process in which a judge could fill the role of the parent. The Court found that "the State has a legitimate interest in the welfare of its young citizens, whose immaturity, inexperience, and lack of judgment may sometimes impair their ability to exercise their rights wisely" (United States Supreme Court 1990). In a friend of the court brief, developmental scientists representing the American Psychological Association, citing substantial behavioral science research, argued that by the age of 14, adolescents have adult-like "abilities outlined in the law as necessary for understanding treatment alternatives, considering risks and benefits, and giving legally competent consent" (American Psychological Association 1989, p. 20). The developmental benchmark of maturity legally required for consent in this case was adult-like cognitive capacity in the context of medical decision-making (Steinberg et al. 2009).

More than a decade after *Hodgson*, another legal case brought issues of adolescent maturity back to the forefront, this time with evidence from developmental neuroscience brought to bear. Nevertheless, as the next section will make clear, a single, unifying, age-based definition of maturity is elusive, despite additional insight provided by the advent of neuroimaging.

Legal Culpability

The juvenile justice system in the USA was created at the turn of the twentieth century as a "therapeutic" alternative to the adult justice system. Premised on the idea that juveniles are immature, it was designed to shepherd individuals whose youthful

indiscretions led them astray safely into adulthood by addressing the underlying causes of their criminality (Feld 1993). Since the 1980s, however, there has been a shift to a more retributive, rather than rehabilitative approach to juvenile justice. Juveniles are increasingly charged as adults and punished accordingly (i.e., more harshly) (Feld 1993; Steinberg 2009). This shift has prompted intense scientific interest in how developmental science might inform culpability and judicial consequences for juveniles (Cauffman and Steinberg 2012). Regardless of age, in the criminal justice system, deficiencies in decision-making capacity or judgment (e.g., impulsivity, short-sightedness) and the presence of coercion each mitigate culpability and reduce the severity of the resulting penalty (Steinberg and Scott 2003). Thus, when considering culpability and consequences for adolescents, it is important to understand developmental changes in impulsivity, planning, foresight, and vulnerability to peer influence, particularly now that juveniles are more likely to find themselves in adult court, or a juvenile system that looks increasingly like adult court.

In 2005, the US Supreme Court Case, *Roper v. Simmons*, focused attention on the intersection of culpability and developmental science (United States Supreme Court 2005). Seventeen-year-old Christopher Simmons was convicted of murder during a robbery committed with friends and was sentenced to death. Simmons' legal team, bolstered by friend of the court briefs from developmental scientists, argued that 17-year olds' still-developing brains make them fundamentally different from adults in terms of legal culpability; consequently, the death penalty should not be imposed on those who commit crimes before age 18 (American Psychological Association and the Missouri Psychological Association 2004). The Court sided with Simmons and overturned the death penalty for juveniles, drawing parallels with prior case law that established those with intellectual disabilities as less culpable. The Court argued that juveniles' "lack of maturity and undeveloped sense of responsibility," coupled with greater vulnerability to and less control over their surroundings, reduced their blameworthiness. Further, while acknowledging the shortcomings of a categorical, age-based definition of maturity, the Court affirmed age eighteen as "the point where society draws the line for many purposes between childhood and adulthood" (United States Supreme Court 2005).

Since *Roper*, the US Supreme has reconsidered the issue of adolescent legal culpability in ways that acknowledge the changing landscape of developmental science. These cases reflect the increasing integration of structural and functional neuroimaging work into the narrative of adolescent immaturity of judgment. In 2010, the Supreme Court decided *Graham vs. Florida* (United States Supreme Court 2010). The case involved Terrance Graham, who was 16 when he committed armed burglary with peers and was given probation without judgment. He was subsequently arrested for additional crimes, his probation revoked, and sentenced to life in prison. On appeal, the Supreme Court overturned life without parole for non-homicide crimes. In its opinion, the Court concluded that "developments in psychology and brain science continue to show fundamental differences between juvenile and adult minds" and cited a friend of the court brief filed by the American Medical Association that highlighted the late maturation of "parts of the brain involved in behavior control" (United States Supreme Court 2010).

Adolescents' immaturity of judgment was again considered by the Supreme Court in *Miller vs. Alabama*, which examined mandatory life sentences for juveniles involved in homicide crimes (United States Supreme Court 2012). This opinion consolidated two state court cases, each of which involved 14-year-old boys who were involved in botched robberies that resulted in homicides. Kuntrell Jackson was convicted for his role in a burglary that resulted in another youth killing a video store clerk. Evan Miller killed his neighbor by setting his trailer on fire after he purchased drugs from him along with another youth. Each boy received a mandatory life sentence.

In its opinion in *Miller*, the Supreme Court required lower courts to consider "an offender's youth and attendant characteristics" in determining appropriate sentencing for juveniles convicted of homicide. The opinion acknowledged the role "science and social science" had previously played in the *Roper* and *Graham* decisions. Further, it cited accumulating scientific evidence in the years since *Roper and Graham* to support developmental risk-factors for criminality, particularly vulnerability to peer influence (Aber et al. 2012; United States Supreme Court 2012). Together, these three cases, *Roper, Graham*, and *Miller* highlight the increasing integration of behavioral and brain science into questions of adolescent culpability and responsibility.

Summary

While informed consent and capability are fundamentally different issues, they focus attention on the same question. When are adolescents' cognitive and socio-emotional capacities sufficiently mature to render them functionally equivalent to adults in terms of decision-making? In an effort to balance competing societal and legal demands, e.g., respecting the privacy of the family to make decisions free from government interference, preserving public safety, promoting public health, and holding individuals responsible for crimes they commit, policy makers and judges have increasingly turned to developmental neuroscience science for guidance. In *Hodgson*, the behavioral science was used to illustrate that adolescents are cognitively mature to make decisions about their health, while in *Roper, Miller*, *and Graham*, a combination of behavioral and neuroimaging science was used to demonstrate that teens are fundamentally different from adults when it comes to impulsivity, planfulness, sensitivity to peer influence, and the brain systems underlying those traits. This seeming inconsistency is explained by evidence that cognitive and socio-emotional processes reflect different domains of maturity with different developmental time courses. We turn now to the scientific evidence that helps to explain this phenomenon.

Brain, Behavior, and Maturity in Adolescence

While there is still much to learn from developmental neuroscience, one question is settled: When it comes the brain, adolescents are not just smaller adults – nor is the adolescent brain a broken or deficient adult brain. Although the adolescent brain has

different features than in childhood or adulthood, across species of social mammals, from rodents to primates, the adolescent brain is well suited to the evolutionary skills required for a successful transition to adulthood (Spear 2000). These include: risk tolerance and novelty seeking needed to venture away from the natal family and try new things, the social affiliation needed to create a new community with peers, and the drive to reproduce in order to pass along one's genes to the next generation (Spear 2000). Although these drives have individual and societal costs, viewed through an evolutionary lens, adolescents' brains are elegantly adaptive.

Normative Brain Changes from Childhood to Early Adulthood

Magnetic resonance imaging (MRI) combines a powerful magnet, radio waves, and sophisticated computer software to produce exquisitely accurate pictures of brain anatomy (i.e., anatomic MRI) and physiology (i.e., functional MRI) without the use of ionizing radiation. The safety of MRI allows not only the scanning of healthy children and adolescents but also repeated scanning throughout the course of development. These features, along with widespread availability of MRI technology, have led to thousands of studies that have dramatically deepened our understanding of the path and influences on brain development in health and illness. Brain tissue on anatomic MRI scans is usually categorized into two main types: (1) gray matter, which is comprised mostly of cell bodies, dendrites, and dendritic processes including synapses – the junctions between communicating brain cells (Braitenberg 2001); and (2) white matter, which is comprised mainly of axons wrapped in myelin – a fatty insulating substance that increases and regulates the speed of neuron-neuron communication.

A key insight provided by MRI studies is that the brain does not mature by becoming larger. It matures by becoming more specialized and more interconnected. By age 6, the brain is already approximately 93 % of its maximum size. The maximum size occurs around age 11 in girls and 13 in boys and then decreases slightly as the demands of the environment optimize brain circuitry – strengthening useful connections and eliminating unused or non-useful connections. The powerful twin processes of overproduction followed by selective elimination drive brain development from conception until death, but the net balance is what tips at around the time of puberty. The pruning process is important in at least two respects: It allows the brain to change in response to the specific demands of its environment, and it facilitates increased specialization of brain regions (Sowell et al. 1999; Rubia et al. 2000; Sowell et al. 2003).

Different parts of the brain follow different developmental courses. Gray matter structures generally follow an inverted "U" trajectory, whereas white matter increases during the first four decades. Structures related to processing information from the five senses – sight, sound, touch, taste, feel – mature early, within the first few months of life. The part of the brain involved in processing incoming speech (i.e., Wernicke's area) matures before the part involved in the production of speech (i.e., Broca's area). Areas involved in integrating activity from parts of the brain

involved in more primary processing mature later (i.e., association areas) and circuitry integrating input from the association areas mature later still (i.e., high association areas). To use a literary metaphor, if the brain components are like letters of the alphabet, maturation proceeds by combining the letters into words, then the words into sentences, the sentences into paragraphs, and so on. The high association areas (e.g., prefrontal cortex) synthesize the lower levels of organization into the higher (e.g., words to sentences; sentences to paragraphs) and continue to change dynamically well into the third decade of life.

It is the relatively late maturation of the prefrontal cortex that has garnered the most attention in judicial realms. Areas of the prefrontal cortex are part of circuitry involved in many of the traits and behaviors most relevant to the issues of informed consent and culpability: (1) controlling impulses; (2) imagining and weighing the consequences of different courses of action (i.e., counterfactuals); (3) delaying gratification; (4) judgment; and (5) long range planning. It is not that these capabilities are absent during the teen years, but they are not as good as they are going to get. Like other features of the adolescent brain, the late maturation of the prefrontal cortex is not inherently a liability. Across species ranging from corvids (e.g., crows, ravens, rooks, jays, magpies) to primates, protracted development and greater time of dependence upon caregivers is correlated with larger brains and greater cognitive capacities (Cluxton-Brock 1991; Holzhaider et al. 2010). The extremely protracted development of *Homo sapiens* allows our species to stay flexible to changing environmental challenges and might have been crucial to our survival.

The Changing Frontal/Limbic Balance

The late maturation of the prefrontal cortex (and other higher association areas) is in stark contrast to other brain structures more laden with hormone receptors that are ignited at the time of puberty. Sometimes referred to generically as “limbic,” these areas are located more centrally in the brain and are involved in circuitry of emotions, reward systems, and drives. The jolt to limbic circuitry at puberty triggers several changes important for our survival. Sex drive becomes prominent to perpetuate our species. Aggression increases to secure and protect resources. Social interactions, one of our most effective survival skills, take on heightened priority.

Compared with adults and younger children, adolescent decision-makers are particularly sensitive to environmental cues, are particularly motivated by rewarding stimuli, and struggle to manage their affective responses (Casey et al. 2008; Somerville et al. 2010). A neural mechanism underlying these tendencies is increased dopaminergic activity in the circuit that connects the amygdala (a limbic structure involved in emotional processing), the ventral striatum (a key component of the brain’s motivational circuitry), and the frontal lobes (Benes 1998; Cunningham et al. 2002; Somerville et al. 2010). The dopamine system is part of a behavioral activation network that alters incentive-motivated acts (Siever 2008; Wahlstrom et al. 2010). The dopaminergic system undergoes dramatic changes during adolescence including a sharp increase in the number of dopamine receptors.

This is consistent with functional MRI studies demonstrating larger activation in the nucleus accumbens, orbitofrontal cortex, and anterior cingulate cortex in response to rewarding stimuli (Wahlstrom et al. 2010).

Several theorists (e.g., Dahl 2001; Steinberg 2007; Ernst et al. 2009) have posited that adolescent risk-taking behavior is related to a temporal gap between this early dopaminergic surge and the “slow and steady” development of the cognitive control system. We can see evidence of this gap in studies designed to probe motivated behavior, delay of gratification, and peer influence. For example, a driving-simulator fMRI study found that when adolescents knew their driving was being observed by peers, they exhibited much greater activation in the reward circuitry (i.e., ventral striatum and orbitofrontal cortex) than when they completed the task without being watched by their peers (Chein et al. 2010). Further, reward activation in the presence of peers was strongly negatively correlated with their self-reported resistance to peer influence (Chein et al. 2010). Notably, adults engaged in the same task were not affected by being observed.

Like the dopamine system, the serotonin system also undergoes substantial changes during adolescence. In addition to its involvement in basal ganglia structures, serotonin also modulates the expression of aggression via actions in the orbital frontal cortex and anterior cingulate cortex. Selective serotonin reuptake inhibitors (SSRIs) may reduce impulsive aggression, and serotonin reduction is correlated with decreased learning of cooperation and a lowered perception of trustworthiness (Siever 2008).

Earlier models explaining behavior as the outcome of a “battle” between limbic and prefrontal cortex influences (e.g., id versus ego) have been replaced by a more nuanced view. In this paradigm, behavior emanates from a synergistic interaction; limbic input prioritizes and assigns meaning for the prefrontal cortex to integrate with past, present, and future considerations when initiating a course of action. Appreciating the interplay between limbic and frontal systems is imperative for understanding decision making during adolescence. If criminality and other risky behaviors were simply linked to prefrontal cortex maturation, one would expect children, not adolescents, to be the main offenders.

Connectivity

The increasing connectivity among disparate brain regions during youth development parallels increasing white matter as the brain progresses from infancy, to childhood, to adolescence, to adulthood. Unlike gray matter, white matter volumes increase more or less linearly throughout adolescence, providing the neural foundation for more complex, integrative cognitive processes (Paus et al. 2001; Anderson 2002). Increasing white matter volumes likely reflect a number of cellular processes (Paus 2010), but most notably, myelination. Myelin, a sheath of fatty cell material wrapped around neuronal axons, allows nerve impulses to travel throughout the brain more quickly and efficiently and helps to regulate the neural activity that facilitates information processing (Fields and Stevens-Graham 2002).

The electrical insulating properties of myelin allow for signals to travel at speeds up to 100× faster than for unmyelinated axons. Also, in myelinated axons, the ion pumps that fuel axonal activation only need to reset the ion gradients at nodes between sections of myelin, instead of along the entire expanse of the axons. This results in up to a 30-fold increase in the frequency with which a given neuron can transmit information. The combination of increased speed (100×) and quicker recovery time (30×) can yield a 3,000-fold increase in the amount of information transmitted per second. This non-trivial impact of myelin on the brain's ability to process information may underlie many of the aspects related to what the Supreme Court described as "immaturity, impetuosity, and failure to appreciate risks and consequences" (Luna and Sweeney 2004; Luna et al. 2010).

Empirical research linking brain anatomy and connectivity to adolescent behavior is beginning to accumulate. For example, individual differences in structural connectivity (i.e., organization of white matter tracts) have been linked to increased willingness to wait for a desired reward (Olson et al. 2009). Similarly, a handful of studies have linked individual differences in brain structure and/or activation to resistance to peer pressure (Grosbras et al. 2007; Paus et al. 2008). For example, in one study, 10-year olds who demonstrated high resistance to peer influence exhibited markedly more functionally integrated neural processes when processing nonverbal social cues than to same-aged children who demonstrated low resistance to peer influence (Grosbras et al. 2007).

Different Context, Different Person? Hot and Cold Cognition

Why, in some circumstances, do adolescents behave, decide, and reason like adults, and in other situations appear to have very limited maturity of judgment? Most developmental researchers agree that adult-like maturity is evident earlier in adolescence for intellectually driven decisions such as whether to seek contraceptives, or treatment for depression than for impulsive, peer-influenced decision-making situations (Steinberg et al. 2009). While long documented in the behavioral science literature (and lamented by parents of adolescents), evidence from structural and functional neuroimaging studies is now helping to provide the neural basis for this duality. The answer lies in the Achilles heel of adolescent maturity: socio-emotional context – particularly the distinction between "hot" and "cold" cognition.

Hot cognition refers to conditions of high emotional arousal, conflict, or peer pressure; this is often the case for the riskiest of adolescent behaviors (MacArthur Foundation Research Network on Adolescent Development and Juvenile Justice 2006). Cold cognition refers to non-stressed decision-making. The biology of "hot" versus "cold" cognition relates back to the interaction between prefrontal cortex and limbic structures. As described above, hot and cold cognition are supported by different neuronal circuits and have different developmental courses (Steinberg 2005). Hot cognitive situations shift motivational circuits into overdrive, leaving bare adolescents' most fundamental cognitive vulnerabilities. As functional connectivity increases between motivational and cognitive control circuits, great socio-emotional maturity, and the ability to reliability demonstrate it, can be expected (Luna et al. 2001).

Neuroethical Cautions and Pitfalls

The promise of a biological explanation for adolescent risk behavior has captured the attention of the media, parents, policymakers, and clinicians alike. There is still, however, much to be learned about how changes in brain structure and function relate to adolescent behavior. A few cautions are warranted.

First, it is important to avoid the ecological fallacy, i.e., using findings about groups of people to make predictions about a specific individual. This is akin to using average monthly rainfall data to predict the likelihood that it will rain on any one day. Neuroimaging studies often create a "composite brain" by combining data from several individuals in order to make inferences. Consequently, neuroscience research is well equipped to address group-level difference in brain structure and function (e.g., sex differences or differences between 20-year olds and 14-year olds). However, it is more complicated to use those brain composites to predict an individual's brain structure, function, or behavior. There have been increasing efforts to using imaging to link individual differences in brain development to behavior, and while these studies show promise, this work is still in its infancy (Dosenbach et al. 2010).

Second, while our judicial system has affirmed age 18 as key legal transition between childhood and adulthood, even at the group level, there is not a sharp transition between age 17 and 18, or "adolescent" to "adult" brain. Further, because the time course of development is highly variable from person to person, a person's chronological age alone may tell us relatively little about his or her level of neurological or behavioral maturity (Aronson 2007).

Third, given the enormous role of context in shaping brain and behavior, some caution is warranted when generalizing from research conducted in the laboratory. Behavior is a function of multiple interactive influences including experience, parenting, personality, culture, psychological well-being, and social relationships (Arnett 1992; Irwin Jr et al. 1992). It remains challenging to create ecologically valid scenarios in the laboratory that replicate the full array of factors that influence behavior generally and maturity of judgment specifically. Thus, an adolescent's performance on laboratory tasks may not reflect the level of maturity he or she would demonstrate in the real world.

The Power of Brain Science

It is tempting to view neuroimaging as means of bypassing the vagaries of human behavior in favor of a more tangible, objective link to an individual's intentions or capacities. Neuroscience wields enormous influence in our current social dialogue. Judges have sometimes been reluctant to allow brain images into the court room, for fear that their visual appeal and scientific aura may be overly persuasive (Hughes 2010). Although the most recent research suggests that brain images per se may be no more persuasive than other ways of presenting findings (e.g., Farah and Hook 2013), neuroscience more generally may exert disproportionate influence. Neuroscience research findings, even if logically irrelevant, increase an

explanation's persuasiveness (Weisberg et al. 2008). Pictures of the brain satisfy our basic need to see, hold, and manipulate concepts that are complex and diffuse, like maturity, development, and motivation. Consequently, brain scans are popularly seen as "hard" evidence, while behavioral science data are seen as subjective. In reality, behavioral scientists and neuroscientists are often telling the same story, but neuroscientists are much more likely to be heard.

Conclusion

The issues of informed consent and legal culpability illustrate the emerging neuroethical challenges and opportunities involved in using neuroscience to inform child and adolescent policy. The use of neuroimaging in policy, in particular, highlights that the complexities of human behavior transcend pictures of the brain. The ability see the brain and to watch it change from childhood to adulthood has been transformative; nonetheless, these pictures do not eliminate the uncertainties involved in balancing adolescents' need for protection and their growing autonomy. At any point in development, the brain reflects a lifetime of interaction among biology, behavior, and environment (Johnson et al. 2009; Johnson and Blum 2012). Similarly, at any moment in childhood and adolescence, the capacities for cognitive and socio-emotional maturity are a function of both characteristics of the brain and characteristics of the decision-making environment. These complexities are rife for misinterpretation, misapplication, and misunderstanding. Brain scientists, ethicists, and legal and medical professionals must balance the need to communicate scientific complexity and uncertainty, with the need to communicate clearly what is not in question; at the threshold to adulthood, the brain is changing, and a continuing policy dialogue about how best to accommodate, support, and understand those changes is essential.

Neuroscience, Gender, and "Development To" and "From": The Example of Toy Preferences

110

Cordelia Fine

Contents

Abstract

"Development to" perspectives implicitly or explicitly assume that experience influences the individual's development "to" a genetically encoded phenotype. By contrast, "development from" perspectives assume no genetically pre-specified developmental pathway, but the co-construction of the phenotype from the complex and dynamic interaction between environmental stimuli, genotype, and the organization of the nervous system at each developmental phase. This chapter examines the "brain organization" account of sex differences in toy preferences in light of challenges to the "development to" perspective, of which the brain organization account is an example. It is argued that there are significant methodological and conceptual issues, and empirical uncertainties, regarding each of four categories of evidence commonly cited as support for the brain organization account. The scientific and

ethical need for research from a "development from" perspective for future investigations of this politically important and socially sensitive scientific question is discussed.

Introduction

Persistent sex differences in social roles, occupations, and occupational success – even in progressive twenty-first century societies – is a phenomenon requiring explanation. As Eagly and Wood (2013) have recently noted, research within behavioral science that ultimately seeks to answer this question has mostly taken place in parallel streams. On the one hand, there are researchers interested in the influence of social factors (such as gender socialization and sex-based discrimination), while others investigate the contribution of biological factors (such as the effect of hormonal and brain differences between the sexes). The conceptual framework for the latter group of researchers is often (either explicitly or implicitly) the prominent and influential "brain organization" theory (for brief overview, see Breedlove et al. 1999; Hines 2010). During gestation, the gene-directed development of testes in the male fetus results in a surge of gonadal fetal testosterone (fT), and this directs the development of male genitalia. In humans, this "critical period" occurs during approximately weeks 8–24 of gestation (Reyes et al. 1973). Brain organization theory, first proposed by Phoenix and colleagues (Phoenix et al. 1959), holds that a second effect of this surge of fT is to permanently "organize" a male brain that produces male behavior (in some cases, after these brain structures are activated by circulating sex hormones in pubescence and adulthood).

Brain organization theory was originally proposed to explain sexually differentiated behavior, particularly behavior tied to reproduction, in nonhuman animals, but it has since been proposed that the organizational effects of fetal testosterone on brain development contribute to human sex differences in sexuality, gender identity, and gender-typed interests (e.g., Hines 2010, 2011; for comprehensive review and critique, see Jordan-Young 2010). Proponents of such brain organization accounts of course acknowledge that social experiences contribute to human sex differences. However, social experience is often implicitly or explicitly represented as playing a merely influential, amplifying, or even interfering role in development, rather than an integral one as co-author of the developing phenotype. Moore (2002) has provided a helpful articulation of the distinction between these differing perspectives, referring to them as "development to" and "development from" approaches, respectively. In the "development to" perspective, there is an underlying assumption that experience merely influences the individual's progress "to" a genetically encoded phenotype. By contrast, according to a "development from" perspective, there is no pre-specified developmental pathway. Rather, every developmental step is constructed from the complex and dynamic interaction between environmental stimuli (including social experiences), genotype, and the organization of the nervous system in a particular developmental phase.

A "development from" approach, with bidirectional genetic, hormonal, neuronal, behavioral, environmental, and cultural influences, is supported by research across each level of analysis of behavior (Li 2003; Lickliter and Honeycutt 2003). This has important implications for neurobiological investigations of sex differences: Gender, as a powerful and pervasive social phenomenon, has material effects on the body and brain (e.g., Fausto-Sterling 2005; Kaiser 2012). One recent example is provided by a large-scale longitudinal study, which found that fatherhood reduced testosterone levels in men. This reduction was greater in fathers who spent more time physical caring for their young offspring (Gettler et al. 2011). The influence on endocrine state of the social construction of gender roles for fathers, in terms of expected contribution to parenting, is also indicated by a comparison of two neighboring cultural groups in Tanzania, which found lower testosterone levels among fathers from the population in which paternal care was the cultural norm, than in fathers from the other group in which paternal care was typically absent (Muller et al. 2009).

Also in line with a "development from" perspective is the growing evidence for neuronal plasticity throughout development. Neuronal plasticity refers to phenomena whereby neuronal characteristics are responsive to external, including social, experiences, resulting in changes such as in neuronal responsiveness, synaptic connectivity, dendritic branching, gene-expression, and gray and white matter volumes (e.g., Draganski et al. 2004; Edelmann and Auger 2011; Fields 2010; Haier et al. 1992; Jäncke et al. 2001; Maguire et al. 2000). Thus, while clearly the brain is not infinitely malleable, neural circuitry develops through, and is altered by, experience (Westermann et al. 2007). Accordingly, the social phenomenon of gender – in which behavior and activities are influenced by stereotypes and norms that are variable across time and place – becomes "part of our cerebral biology" (Kaiser et al. 2009, p. 57).

Importantly, a "development from" perspective makes clear the error of conceptualizing variables such as hormonal level, hormonal effects on brain or behavior, or neural function or structure, as pure biological variables. Rather, they are intertwined with the individual's life-history and current social context, and sex difference research that proceeds without this insight runs the risk of being misleading and/or uninformative. As Moore (2002, p. 65) pointed out in relation to research conducted within the brain organization framework, research strategies that work from a "development to" perspective, and therefore observe only early hormones and later behavioral outcomes, leave "lots of unexplored territory and many possible pathways, perhaps convoluted ones, from the early hormones and end points of interest." In other words, such strategies neglect to investigate the complex, dynamic process of development itself. Moore's work, demonstrating the unexpectedly complex effects of early testosterone on sex-differentiated brain stem characteristics and sexual behavior in rats, has provided an increasingly well-known (although long ignored, see Kaplan and Rogers 2003) example of the problematic nature of a "development to" research approach. Mother rats are attracted to odor cues from the higher levels of testosterone in the urine of males and, therefore, lick and groom male pups more than they do female pups.

Remarkably, this differential maternal treatment of males and females contributes to low-level sexually differentiated brain structure and sexual behavior (Moore 1984; Moore et al. 1992). According to the standard brain organization account, these brain and behavioral differences would be attributed solely to the direct action of early testosterone on the brain.

In light of these challenges to the "development to" perspective implicit in the brain organization account, this chapter examines an important and influential hypothesis derived from the brain organization account. This is the claim that sex differences in fetal testosterone, via permanent effects on brain structure, create inherent differences in sex-typed interests that are reflected in male/female differences in toy preferences in childhood. This behavioral difference is among the most substantial observed in childhood, and exceeds those found in cognition and personality (Hines 2010). Four lines of research are repeatedly put forward as evidence for a brain organization account of sex differences in toy preferences. First, it is argued that sex differences in visual interest in a social versus mechanical stimulus exist even in the first few days of life, prior to either the development of gender identity or exposure to significant gender socialization processes. Second, females with the genetic condition of congenital adrenal hyperplasia (CAH), who are exposed to atypically high levels of fetal testosterone during gestation, show more male-typical toy and activity preferences than do non-affected female controls. Third, it is claimed that sex differences in toy preferences similar to those observed in human children are also found in rhesus and vervet monkeys. Fourth, correlations have sometimes been observed between markers of fetal testosterone levels (taken during the critical period) and later gendered play preferences. These four lines of evidence are regularly presented, both in the scientific literature as well as in popular accounts, as showing that the brain organization account of sex differences in toy preferences is beyond reasonable doubt (e.g., Hines 2011; Hoff Sommers 2012; Orenstein 2011; Saad 2012; Wong et al. 2012).

However, the discussion above raises a priori reasons to suppose that such a conclusion may be premature; and, in fact, substantial methodological and conceptual criticisms have been made of each of the lines of evidence marshaled in support of the hypothesis. The following sections briefly summarize findings, and review and expand critiques of these studies' methods and conclusions. The final section argues, on both scientific and ethical grounds, a need to better take these criticisms into account, and deploy a "development from" perspective in future research.

The Brain Organization (Masculinization) Account of Sex Differences in Toy Preferences

Many toys enable children to role-play adult activities, and some of these activities and their associated toys are more strongly linked with one sex than with the other (e.g., dolls and tea-sets vs. trucks and guns). Although many behavioral differences between the sexes are modest both in children and adults (Hyde 2005),

from 3 years of age there are substantial sex differences in toy preferences. For example, in a typical lab-based observational study, children were offered a collection of female-typical, male-typical, and neutral toys to play with. Girls spent about 60 % of their playing time with female-typical toys (a set of dishes, a Barbie doll with clothing and accessories, a rag doll with accessories and a cosmetics kit), while boys spent only 6 % of their time on those toys. By contrast, the boys spent 70 % of their time with male-typical toys (a car, a fire-truck, a Lego airplane or Lincoln Logs construction toy, a tool set, a helicopter and a gun), compared with only 13 % for girls (Pasterski et al. 2005). Girls and boys spent similar amounts of time playing with the neutral toys (a puzzle, a board game, books, crayons, and a sketchpad). Parents also report sex differences in questionnaires about their children’s sex-typed childhood activities and interests (e.g., Hines et al. 2004).

Why do these sex differences in toy and activity preferences exist? Self-socialization perspectives emphasize the salience and importance of gender in the social world (Bem 1983), and the motivating effect of this on children, who play an active role in their own gender development once they become aware of their gender identity at about 2 years of age (e.g., Arthur et al. 2008; Bigler and Liben 2007; Martin and Halverson 1981). The salience and functional importance of gender is also a component of social learning perspectives on toy preferences, although these emphasize instead the role of others (such as caregivers) in modeling, channeling, and reinforcing stereotype-consistent behavior (e.g., Bussey and Bandura 1999). These accounts therefore anticipate the appearance of sex differences even prior to the development of gender identity.

However, the brain organization account makes the additional proposal that innate brain differences, arising from sex differences in exposure to fT, contribute significantly to gendered toy preferences. Sex differences in prenatal testosterone levels are suggested to provide the “seeds” of later male/female differences in toy preferences, with “nurture” progressively recruited in ways that amplify these initial psychological biases (Alexander and Wilcox 2012; Baron-Cohen 2007; Berenbaum and Resnick 2007). As to what those psychological biases might be, Alexander (2003) suggested that males are born predisposed to be attracted to movement (since this would have advantaged them in developing hunting skills in prehuman and early humans societies), while females are born predisposed to be attracted to reddish-pink colors and rounded forms evocative of infants (since this would have advantaged them in developing infant nurturance skills). Related suggestions are that males might be more drawn to objects that allow for active play (see Alexander and Saenz 2012), or that they have “[i]nnate predispositions for perceptual attributes or motor affordances of objects” that bias them toward objects or activities that allow for propulsive movement (Benenson et al. 2011, p. 263). A second influential proposal, the Systemizing/Empathizing hypothesis, is that higher levels of fT predispose the (typically) male baby toward understanding and building rule-driven, input-function-output systems. By contrast, lower levels of fT predispose (typically) female infants to attend to empathy-related stimuli; namely,

people (Baron-Cohen 2003). As noted earlier, four lines of research are repeatedly put forward as evidence for a brain organization account of sex differences in toy preferences, and these are each now discussed in turn.

The Newborn Study

While a number of studies have looked for sex differences in toy preferences in infants, intended or unintended gender socialization processes, such as caregiver responses and familiarity effects, could potentially underlie any differences observed. To exclude this as a possibility, a much cited study compared neonates' looking time at a live face versus a mobile (Connellan et al. 2000). These stimuli were chosen to reflect interest in biological/social motion versus mechanical motion. Male and female babies both spent approximately half of the total presentation time looking at the face, which was that of the first author. However, males looked longer at the mobile than did females (52 % of presentation time vs. 41 % for females) and females looked longer at the face than at the mobile. These findings have been interpreted both by the study authors and others as evidence for "innate" sex differences in psychological interests.

However, serious concerns have been raised over the considerable methodological flaws of this study (Nash and Grossi 2007). These include the many differences between the stimuli (any of which could have been responsible for the observed differences), and nonstandard procedures for measuring looking time preference (such as serial rather than simultaneous presentation) and, in particular, the scope for experimenter expectancy effects. The first author was both the face stimulus and controlled the movement of the mobile, yet inadequate efforts were made to ensure that the experimenter was blind to the baby's sex. These are serious methodological shortcomings; moreover, the study has never been replicated. Indeed, a recent study of 4–5 month-old infants, that used a number of different face versus object stimuli, found that both girls and boys preferred faces (Escudero et al. 2013). In addition, no evidence is provided that a newborn's visual preference in this experiment anticipates his/her future abilities and interests: It is an assumption that is "essentially unargued for" and "questionable at best." (Levy 2004, p. 322; see also Nash and Grossi 2007). Indeed, it seems to implicitly assume that newborn visual preference is an early indicator of a future biologically pre-specified developmental outcome.

Toy Preferences in Females with CAH

The toy and activity preferences of females with CAH are of considerable interest to researchers, since they provide a group in which high levels of fT exposure are separated from social rearing as a boy. Studies investigating the toy preferences of females with CAH typically use parental and retrospective self-report questionnaires, and lab-based observational studies. Preferences are compared with those of boys and unaffected female relative controls. For example, studies have compared

scores on the Pre-School Activities Inventory (PSAI), which measures interest in toys and activities, and display of characteristics, that are differentially observed in boys and girls (Golombok and Rust 1993). Both questionnaire and observational studies have consistently found that females with CAH show a stronger preference for male-typical toys and activities, and less interest in female-typical ones, compared with unaffected female relative controls (e.g., Berenbaum and Hines 1992; Hines et al. 2004; Nordenström et al. 2002). For example, Pasterski et al. (2005) found that girls with CAH spent only 21 % of time playing with female-typical toys (compared to 61 % for unaffected girls), and 44 % of time with male-typical toys (compared to 13 %).

These findings are often regarded as providing definitive support for a brain organization account of toy preferences. However, these studies do not directly test its predictions. Clearly, the most appropriate way to test such hypotheses would be for researchers to categorize (or create) toys on the basis of the presence or absence of the features thought to be critical: object features such as movement, color, and form (Alexander 2003); affordance for active play (Alexander and Saenz 2012); or stimuli that represent rule-driven, input-function-output systems versus empathy-related stimuli (Baron-Cohen 2003). Instead, stimuli sets are created on the basis of their popularity with males versus females, a strategy criticized decades ago by Bleier (1986, p. 150) for its presumption that culturally defined masculinity is “as objective and innate a human feature as height and eye color.” Thus, when researchers observed that an assumedly “male-typical” toy (the Lincoln Log construction toy) was very popular with control girls, it was eliminated from the male-typical set (Pasterski et al. 2005). Clearly, if it had been chosen a priori on the basis of the presence of features thought to be intrinsically appealing to a masculinized brain, this would have instead constituted counter-evidence to the brain organization account. This approach is problematic, because the features supposedly attractive to a masculinized (non-masculinized) brain are neither exclusive to, nor always present in, male-typical (female-typical) toys. Toy vehicles can be moved, but so too can toy vacuum cleaners, prams, and pull-along toys, none of which are particularly associated with boys. Guns and construction toys do not afford movement more than, say, tea-sets. Cosmetics invite systemizing, since they involve the transformation of an input (the “before” state) into an output (the desired “after” state) via a function (the application of cosmetics). In addition, neither cosmetics nor jewelry are necessarily associated with reddish-pink colors, round features, or empathizing. Stuffed animals, by contrast, have some of these features, yet are rarely used as female-typical toys and are sometimes instead categorized as neutral toys.

Furthermore, neutral toys often arguably have attributes that should be differentially attractive to males and females, according to the Empathizing/Systemizing account (Fine 2010). For example, puzzles, board games, and books are frequently used as “neutral” toys. However, puzzles and board games are arguably “systemizing” activities, and are indeed referred to in a questionnaire designed to measure systemizing tendencies in children, the SQ-Child (Auyeung et al. 2006). In addition, books could arguably be categorized as an empathizing toy, at least in cases

where the book presents characters and their thoughts and emotions (either in text or illustration, depending on the age group under study). Similar issues arise when considering the use of the PSAI. Notably, the questionnaire was not developed to test brain organization accounts of play preferences, but rather to assess gender role behavior in pre-school children. It contains numerous items assessing behaviors that are presumably outside the scope of proposed effects of fT on the intrinsic value of object properties: e.g., interest in jewelry and pretty things, pretending to be a female character, avoidance of getting dirty, and dressing up in girlish clothes.

Thus, the current research approach makes it impossible to distinguish a brain "masculinization" explanation of findings, in which particular characteristics of toys are intrinsically more appealing to boys and females with CAH, from the alternative possibility that females with CAH are less attracted to whatever happens to be culturally ascribed to females and/or more attracted by a cultural ascription with males. This is an importantly different proposition, and there are good reasons to take this alternative account seriously. Gender identity in females with CAH is generally unremarkably female, but nonetheless differs modestly to that of female controls, with slightly more male identification and greater expression of dissatisfaction and unhappiness with a female gender identity (e.g., Berenbaum and Bailey 2003; Meyer-Bahlburg et al. 2006). Moreover, Jordan-Young (2010, 2012) has argued that, in their focus on prenatal hormone exposure, researchers have overlooked other variables also affected by the condition that plausibly influence psychosexual development. These include intensive medical and psychiatric intervention arising from atypical or masculinized genitalia, other physical effects of the condition inconsistent with cultural ideals of feminine attractiveness (such as hirsute appearance and short, heavy stature), and the priming of expectations of masculinity in parents, the girls themselves, and others. To date, the possible role of these other factors in the development of masculinized toy preferences has scarcely been investigated. Research in this direction is currently limited to questionnaires or observations of parental attitudes and behaviors regarding sex-typical and atypical play, the findings from which have been inconsistent (Berenbaum and Hines 1992; Pasterski et al. 2005; Wong et al. 2012), and represent only very early first steps in adequately acknowledging the physiological and psychological sequelae of the condition, as well as understanding how labeling, priming, and expectation effects arising from a diagnosis of CAH might, in complex and iterative ways, affect psychosexual development (see Jordan-Young 2012).

Sex Differences in Toy Preferences in Monkeys

Two studies of toy preferences in monkeys are often cited as support for the idea of "inborn" sex differences in predispositions toward different toy types. The first, an observational study of vervet monkeys' toy play behavior, compared contact time with male-typical toys (a ball and police car), female-typical toys (a toy pan and a doll), and neutral toys (a picture book and a stuffed dog), presented serially to groups of vervets (Alexander and Hines 2002). (As Jordan-Young (2010) has noted,

this procedure meant that any one individual vervet's choices were dependent on what other vervets were already playing with.) Between-sex contrasts showed greater male interest in the male-typical toys, and greater female interest in the female-typical toys. The sexes showed equal interest in the neutral toys. Within-sex contrasts found only that females had greater percentage contact with female-typical toys than with male-typical toys. A second study with rhesus monkeys compared interaction (using two dependent variables, total frequency and total duration of contact) with wheeled toys versus stuffed toys (Hassett et al. 2008). Between-sex contrasts found that males and females were equally interested in the wheeled toys. Males and females also spent a similar duration of time with the stuffed toys, but females had a greater total frequency of interaction with these toys. Within-sex contrast revealed that males preferred wheeled toys over stuffed toys, while females showed no preference.

As with the studies of females with CAH, interpretation of these two studies is complicated by the non-hypothesis-driven fashion in which toys have sometimes chosen by researchers. In particular, this approach has enabled male-typical, female-typical, and neutral toys to be categorized differently across studies, with the unintended effect of making findings appear more consistent than they actually are (see Jordan-Young 2010). For example, Servin and colleagues (Servin et al. 2003) classified a ball as a "neutral" toy, and it was the most popular toy (when presented with a choice between a car, ball, and doll) among (control) female girls. However, balls were categorized as a male-typical toy in the vervet monkey study. Similarly, a stuffed animal was a neutral toy in the vervet study, but the sole type of feminine toy in the rhesus monkey study. Importantly, male vervet monkeys played more with the stuffed dog (their favorite toy as a group) than with the car – this is in direct contradiction with the main finding of the rhesus monkey study.

An additional issue with the choice of toys for the monkey studies is that such stimuli are unlikely to hold the same meaning to monkeys as they do to human children, and the "affordances" monkeys might perceive in them are more assumed than proven. For example, as Jordan-Young (2010, p. 236) points out, "[h]ow does a vervet know that the purpose of a cooking pot is not to bang it, throw it, or use it to whack another vervet?" Jordan-Young has noted that although that study's findings were accompanied by a photo of a male vervet rolling the toy car along the ground, and a female vervet cradling the doll, the frequencies of such behaviors in each sex were not reported. Similarly, Hassett and colleagues chose stuffed animals versus wheeled toys to elicit evidence of different activity preferences, but although data were collected on the specific kinds of behaviors directed toward toys, these were not reported. It is therefore unknown whether, for example, stuffed toys tended to be nurtured, bitten, or thrown (indeed, one trial had to be terminated early when a stuffed toy "was torn into multiple pieces"), or whether play with wheeled toys was more active or involved more object movement than play with stuffed animals. A recent study with young children found that play with female-typical toys was as active as play with male-typical ones (Alexander and Saenz 2012). Furthermore, as Ah-King (2009) has noted, since vervet monkeys

are tree-dwelling vegetarians, it is unclear why males in particular should show a predisposition for the development of hunting skills. Rather, the ability to navigate in space would be necessary for survival in both sexes.

One final point of criticism targets the assumption that sex differences in monkeys' toy preferences cannot be attributed to socialization processes (see Fine 2010). Like humans, primate societies have norms regarding sex roles (such as who gets food, cares for infants, etc.), and these norms can differ across, or even within, species (Burton 1977). For example, male involvement in infant rearing can range from absent to highly involved, even within the same species (Itani 1959; Burton 1992). Burton (1992, p. 45) reported extensive and lengthy male care of young in a Gibraltar troop of macaque species, with young females "kept away from infants so that young males may learn their role." She also observed imitation of infant care by the head male, by male subadults only, who then themselves became involved in infant care (Burton 1972). Interestingly, the behavior of male and female monkeys toward infants only starts to diverge at about 2–3 years of age (Mason 2002) and manipulations of fT exposure (both blocking in males, and increased exposure in females) have no effect on subsequent interest in infants (Herman et al. 2003). These findings indicate non-determination of roles by hormones, a significant role for social learning of sex roles, and challenge the assumption that sex differences in monkeys in play with infant-like toys, for example, must reflect "pure biology," absent the influence of socialization.

Associations Between Markers of Fetal Testosterone and Toy Preferences

A fourth category of studies regularly referred to are those that look for correlations between fT exposure and later gendered play preferences in childhood. The advantage of these studies is that they are based on nonclinical samples (although, in the case of populations who are sampled from mothers undergoing amniocentesis, they are not necessarily representative). Various markers of fT have been used (since ethically it is not possible to sample blood from the fetus unless medically indicated): Amniotic testosterone (aT) is sampled from the amniotic fluid during the procedure of amniocentesis; maternal testosterone (mT) is sampled from the mother's blood; and maternal sex hormone-binding globulin (SHBG), which limits T's functional effectiveness by binding with it, has been used as an inverse proxy for levels of unbound, functionally effective T.

To date, four studies have related markers of fT to later toy preferences (recently summarized in Grossi and Fine 2012, see Table 4.1). The first study assessed behavior using the PSAI and used both mT and maternal SHBG levels as proxies for fT exposure (Hines et al. 2002). In girls only, higher levels of mT (but not maternal SHBG) were associated with more masculine scores on the PSAI. The effect size was very small, explaining only two percent of the variance in score, and no other relationships were significant. (The possibility that mothers with higher vs. lower T levels might create different social experiences that influence their

daughters’ gendered preferences does not appear to have been considered.) Subsequently, Knickmeyer et al. (2005) looked for a relationship between aT and sex-typical play in 4 and 5 year old children, as measured by a questionnaire. No relationship with aT was found in either sex, or in both sexes together. Van de Beek and colleagues explored relationships between mT, aT, estradiol, and progesterone levels and observed play behavior in 13-month-old infants (Van de Beek et al. 2009). They found no relationships with aT, mT, or estradiol. Surprisingly, higher levels of amniotic progesterone were associated with a stronger preference for male-typical toys. Finally, in contrast with these mostly negative findings, Auyeung and colleagues, with a larger sample size, found correlations in both sexes, individually as well as pooled, between aT and PSAI score (Auyeung et al. 2009). It is unclear why this study, with a sample approximately one-third of the size of Hines et al. (2002), found a relation with males that was absent in the earlier study (see Jordan-Young 2010), and whether future work will support these positive relations.

A fifth study, an investigation of Baron-Cohen’s (2003) Systemizing/Empathizing hypothesis, looked for the predicted relations between aT and tendency to prefer systemizing activities in children, using a parental-report questionnaire, the SQ-Child (Auyeung et al. 2006). aT was significantly associated with SQ-Child score (which was greater for boys than for girls), both across the whole sample and for boys and girls separately. However, in addition to the subjectivity of parental report as opposed to observed behavior, only a small number of the items appear to reflect “the drive to analyze or construct systems,” with many items instead appearing to tap into a drive for order, routine, or arrangement of objects (Auyeung et al. 2006, p. S124; see Fine 2010; Grossi and Fine 2012).

One critical concern with these studies is that there is currently no satisfactory evidence that either aT or mT is related to actual fT exposure. In their review of this issue, van de Beek et al. suggested aT as the best index of fT exposure, but acknowledged the lack of knowledge regarding the relationship between levels of aT (the main source of which is fetal urine) and levels in the fetal blood (van de Beek et al. 2004). Indeed, one study that measured mT, aT, and fT between 15- and 23-weeks of gestation found no correlations between the three measures (Rodeck et al. 1985). A more recent clinical study did find that fT correlated with mT (Gitau et al. 2005). However, mT levels are not higher in women pregnant with boys than in those pregnant with girls (Hines et al. 2002; Rodeck et al. 1985), which suggests that “maternal serum androgen levels are not a clear reflection of the actual exposure of the fetus to these hormones” (van de Beek et al. 2004, p. 664). That markers of fT may not correlate with actual fT exposure is of considerable concern in terms of interpretation of findings (Fine 2010).

Conclusions and Future Directions

As noted earlier, a brain organization account of sex differences in toy preferences is regularly presented as though it were beyond reasonable doubt. Yet as this chapter has shown, there are significant methodological and conceptual issues,

and empirical uncertainties, surrounding each of the four categories of evidence. There is considerable tension between the brain organization account and the rejection of "development to" models within developmental science, and Jordan-Young (2010) has comprehensively documented the empirical inconsistencies and contradictions of the data supposedly supporting brain organization theory as applied to humans (see also Fine 2010; Grossi and Fine 2012).

Moreover, more generally, the scientific assumptions implicit in "development to" based accounts – that brain circuitry is largely fixed by a genetic blueprint, that there is unidirectional, causal pathway from genes to behavior via hormones and brains, and that evolution has left us with brains and mental processes strongly reminiscent of our Paleolithic ancestors – have been widely rejected following conceptual and empirical upheavals in the relevant scientific fields (see Fine et al. 2013). A "development from" perspective is more consistent with contemporary perspectives that humans have evolved an adaptively plastic brain that is responsive to environmental conditions and experiences, and the modulation of endocrine function by those experiential factors contributes to that plasticity (for relevant reviews, see Brown et al. 2011; Lickliter and Honeycutt 2003; May 2011; van Anders and Watson 2006). Together with evidence of the considerable variation, across time and place, in gender roles (see Wood and Eagly 2013), the need to question implicit assumptions – such as that current, Western categorizations of toys as masculine and feminine correspond precisely with innate predispositions, or that social learning can be overlooked when considering the behavior of nonhuman monkeys – becomes more obvious. The need to question implicit or explicit "development to" assumptions will be no less important as researchers attempt to relate fetal endocrine exposure to later brain states (e.g., Lombardo et al. 2012).

Children's play worlds are society writ small, and scientific accounts of how and why sex differences in play preferences develop therefore have important political ramifications. Continuing to ignore critiques of the research not only has scientific implications, but also political and ethical ramifications in terms of which groups benefit from what knowledge is produced, as well as from what knowledge is not produced (Haslam and McGarty 2001). Since power hierarchy and inequalities are embedded in gender as a social system, a scientific claim that presents gendered preferences as to some extent "innate" is not politically or socially inert. Brain organization accounts propose that prenatal hormones provide an initial "seed." This initial biologically based "seed" then recruits experience, as the child seeks out the kinds of toys and activities s/he finds most rewarding (although it is generally acknowledged that this is amplified by gender socialization processes). Thus, Baron-Cohen (Baron-Cohen 2007, p. 169) refers to socialization factors "amplifying" what is innately specified, and argues that "we should not expect the sex ratio in occupations such as math or physics to ever be 50–50 if we leave the workplace to simply reflect the number of applicants of each sex who are drawn to such fields." Berenbaum and Resnick (2007) describe hormonal influences as furnishing the "seeds of career choices" (p. 147), and "propose that sex-related career choices and outcomes arise through the mediating and moderating effects of socialization on sex-hormone-influenced individual differences in behavioral development." (p. 148).

Similarly, Alexander and Wilcox (2012, pp. 400–401) refer to hormonally produced “sex-linked dispositions that represent ‘seeds’ of later behavior,” and suggest that sex differences may be smaller in infancy than later in development “when expressed behavior presumably reflects the further influence of experiential factors.” Popular accounts of the social implications of the data often similarly subscribe to the compounding sex-segregation of interests, as “nature” recruits “nurture” (e.g., Hoff Sommers 2012). Importantly, since the “development to” perspective conceives of a unidirectional causal pathway from genes to hormones to brain to behavior, the biological is seen as causally primary in the developmental pathway. This privileging of the biological as somehow more “real” than social contributions is illustrated by the recent comment, by a leading researcher from the brain organization perspective, that research into sex differences in toy preferences “reveals both how humans develop, and how societal pressures act upon children.” (Hines 2013). That is, there is “real” (i.e., biologically based) development that social experiences then merely acts upon.

Brain organization accounts therefore see an original, “essential” difference between the sexes, which is then amplified by experience in a developmental cascade. Such “essentialist” views are associated with increased gender stereotyping, self-stereotyping, stereotype threat, and comfort with the gender status quo (see Fine 2012; see ▶ Chap. 91, “Sex and Power: Why Sex/Gender Neuroscience Should Motivate Statistical Reform” in this volume). While scientists may prefer to think that political and ethical values lie outside their domain of consideration, as the foregoing discussions indicate, such values are implicitly at work in the research questions that are asked, the rigor of the methodologies chosen, the background assumptions made, the emphasis on certain findings over others, and assessments of the uncertainty that is considered tolerable in order for a particular conclusion to be drawn (Douglas 2008; Haslam and McGarty 2001). Importantly, the future research directions that naturally arise out of the critiques presented here could all potentially produce knowledge that challenge an essentialist account of sex differences in toy preferences. For example, hypothesis-driven selection of toys based on the presence or absence of supposedly critical features (rather than cultural association with males vs. females) could potentially produce data that strongly challenge the brain organization account in a way that the current research approach cannot. It is noteworthy that such studies have never yet been conducted, despite Bleier’s critique of the standard approach nearly 30 years ago (Bleier 1986). Interestingly, the few recent studies that have investigated whether particular features of toys differentially appeal to males and females have not supported brain organization account proposals that females are drawn to pinkish-reddish colors (Jadva et al. 2010) or that males are drawn to toys that afford active play (Alexander and Saenz 2012), although Benenson et al. (2011) found sex differences in imitation of propulsive action in 6–9 month-old infants. Similarly, nonhuman primate research, building on recent findings from the social learning literature that these animals show discrimination in who they learn from (Mondragón-Ceballos et al. 2010; van de Waal et al. 2010), could seek to answer the question posed by Hines and Alexander (2008, p. 479): “if some animals of one sex could be trained to use a particular object, would others of that sex model

them?" Together with comparisons between groups with different sex role norms, again, such data could potentially destabilize the conclusion that human sex differences in toy preferences are "innate" and inevitable. Finally, in contrast with a "development to" perspective, a "development from" perspective allows for the possibility that, as is observed in animal hormonal studies, "an early push in a certain direction can be *either enhanced or entirely eliminated* by subsequent experience, such that development from that point forward would proceed as though the early hormone exposure had never happened." (Jordan-Young 2010, p. 288, emphasis in original). Greater attention needs to be paid to the complex and dynamic process of development itself when it comes to toy preferences (for discussion, see Fausto-Sterling et al. 2012).

In summary, for both scientific and social reasons, researchers need to incorporate a "development from" perspective that brings a conceptually sophisticated understanding of both development and gender to this politically important and sensitive scientific question.

Neuroethics of Neurodiversity

111

Simon Baron-Cohen

Contents

Abstract

The concept of neurodiversity is relatively recent and has important ethical implications in signaling that there is no single way to be "normal." In this chapter I explore this notion in relation to the neurodevelopmental condition of autism, taking a historical approach to show how attitudes have changed in parallel with changes in who is recognized as having autism and the emergence of an "autism rights" movement.

From Normality to Typicality

If we go back even as far as 20 years ago, we can see that the concept of "normality" was both widespread and categorical. In clinical research, it was common to compare those with a diagnosis to those without, the former being described variously as "patients" or as "impaired" or "pathological," the latter being described as "normal controls." This binary view of the population assumed all those in the "normal control group" were similar to each other (hence categorical) and implied that those in the other group were by definition "abnormal." The clinical and academic profession of

psychology even had a whole subdiscipline called “abnormal psychology” with textbooks dedicated to this view of those who were not normal.

What changed was both subtle and gradual. In terms of subtlety, the term “normal” gradually gave way to the less value-laden term “typical” as a way of describing those without a diagnosis. It is a more neutral term because it describes some statistical norm or average, which by definition is more common than those at the extremes. In this sense, “typical” simply means more common, and the contrast group is no longer referred to as “abnormal” but as “atypical.” (In recognition of this, in 2008 I changed the title of the course I teach at Cambridge University from its historical name “abnormal psychology” to its current name “atypical psychology.”). A second way in which concepts subtly changed was to connect with the field of *individual differences*, previously mainly restricted to those who studied the dimension of IQ or those who studied personality dimensions. The importance of this was to acknowledge differences even within the typical group and frequently to recognize that those who have a diagnosis are simply an extreme on a dimension of individual differences. This marked a moving away from categorical diagnosis to dimensional diagnosis.

The Autism Spectrum

A very clear example of this is in the field of autism. Autism is a neurodevelopmental condition of partly genetic origin, affecting brain growth, structure, and function. In turn it leads to altered information processing, causing a disability in social relationships and communication but a remarkable attention to detail, unusually narrow interests, a strong need for repetition and routine, and an aptitude for detecting patterns.

Previously it was easier to maintain the belief that autism was categorical because most cases identified not only showed the above features of autism but they also had below average IQ (therefore learning difficulties) and language delay. With this “triple hit” of disability, it seemed plausible that they might be qualitatively distinct from the rest of the population. But during the 1990s, this categorical view became harder to sustain, not least because individuals with autism were being identified at every subtle gradation on the IQ range. While the convenience was to define someone with autism as having delayed language (not speaking by 2 years old) and frequently below average IQ (more than 2 standard deviations below the population mean of 100, so below 70), it became more and more difficult to defend this portrait of autism. This is because there were individuals who had an IQ above this level and who were (for a time) referred to as “high functioning.” In parallel with “admitting” more and more higher functioning individuals into the category of autism, we were also “admitting” individuals with no trace of language delay (they might even have had the opposite pattern, of speaking precociously, with an adult-like vocabulary) and even with an above-average IQ.

“Asperger syndrome” was the name given to individuals with the core signs of autism but with average IQ (or above) and intact language development.

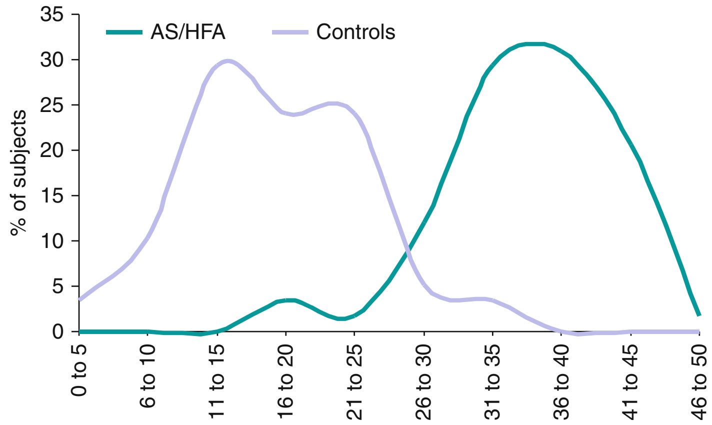

Fig. 111.1 The Autism Spectrum Quotient (AQ)

Uta Frith's book entitled "Asperger Syndrome" and published in 1991 was perhaps the first book in English on this subject and included a translation of Hans Asperger's description of the children who today have a diagnosis of Asperger syndrome. This followed on the wave of interest generated by Lorna Wing's (1981) article in Psychological Medicine introducing Asperger syndrome to the English-speaking biomedical community. But the gradual effect of clinics worldwide starting to diagnose children and adults with Asperger syndrome, as part of the autism spectrum, was to drive home the individual differences approach (such individuals seeming to be the bridge between classic autism and those without a diagnosis) as well as to raise the serious possibility that Asperger syndrome was nothing more than the extreme end of a single dimension.

The publication of the Autism Spectrum Quotient (AQ) in 2001 was one of the first clear demonstrations that autistic traits lie on a continuum on which we can all be scored (Baron-Cohen et al. 2001). The AQ, a questionnaire which probes five different domains of behaviors, preferences, and interests including social skills, attention switching, communication, imagination, and attention to detail, is normally distributed, and – as shown in Fig. 111.1 – those without a diagnosis lie under the left-hand curve, while those with a diagnosis lie under the right-hand curve. Most importantly, these two curves overlap, reminding us that there is no clear point at which those with and without a diagnosis can be neatly separated. This offered strong confirmation of what Lorna Wing had in 1988 called "the autistic spectrum."

Different Ways to Be "Normal"

If in the population people simply vary in terms of the number of autistic traits they have, in what sense can we call someone "normal" and someone else "abnormal"? The very notion collapses as people without a diagnosis differ from each other as much as people with a diagnosis. And of course, autistic traits are not the only kind

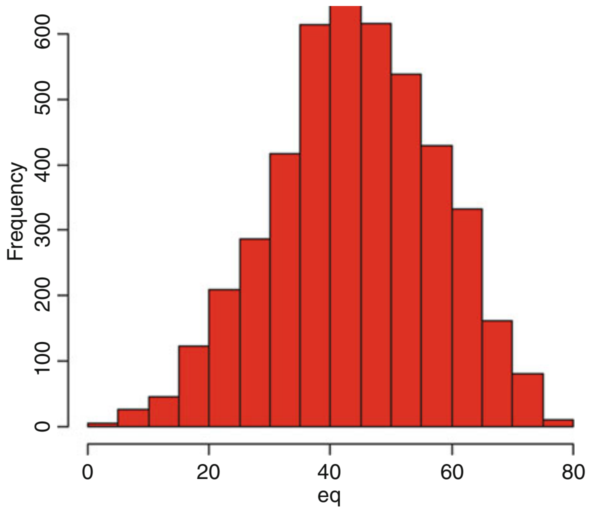

Fig. 111.2 Data from the Empathy Quotient (EQ)

of "diversity" that one finds in the population. The first example includes handedness (left handedness is thankfully no longer seen as "abnormal" or "sinister," and children are thankfully no longer forced to write with their right hand, as I was as a child), and even the notion of left vs. right handedness is challenged, as it has become clearer that being strongly right handed and left handed are just two possible positions on a dimension of individual differences, ambidextrous individuals being a third position, but with people in the population being found in intermediate positions between these clearer points. The second example is sexual orientation, where "gay" or "straight" turn out to be too simplistic a binary classification, given the existence of "intermediate" forms (bisexuality, other). The third example is how easily a person can empathize (reflected in the empathy bell curve that results from using another measure, the Empathy Quotient (EQ), in the population (see Fig. 111.2). And the final example would be individual differences in systemizing drive (the drive to analyze or build a system), as reflected in data from the Systemizing Quotient (SQ).

Given that all of these dimensions of individual differences correlate with differences in brain structure and function (e.g., Lai et al. 2011), it must mean that there are many different ways to develop, many different routes to adulthood, and many ways to function, hence the notion of neurodiversity.

Extending Neurodiversity to Those with a Clinical Diagnosis

If typical individuals manifest neurodiversity, it is only a small step to extend this notion to those with a diagnosis. The radical but quite reasonable proposal from the neurodiversity movement is that those with a diagnosis are simply developing differently, not necessarily worse (or better) than others, but simply different.

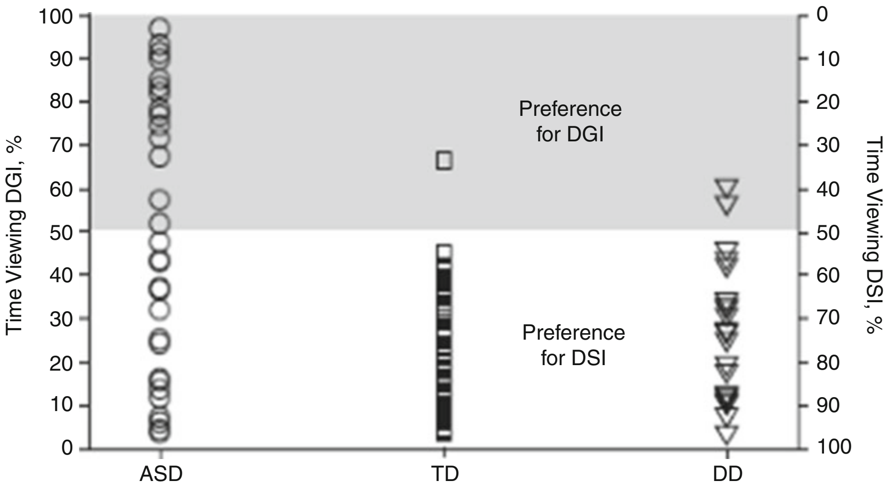

Fig. 111.3 From Pierce et al. (2011)

The benefit of this view is that it makes space for precocious rates of development just as much as delayed rates of development, and it avoids value judgments implicit in the terms "normal" and "abnormal." If we continue to consider autism as our example, we can view children or adults who receive this diagnosis as simply different in their patterns of interests.

A nice study from Karen Pierce and colleagues in San Diego measured how long toddlers with and without autism looked at social (e.g., pictures of children playing) vs. a nonsocial stimuli (e.g., moving geometric figures). They found that more toddlers with autism ("ASD" in the graph) looked for longer at the nonsocial stimulus, and more typically developing toddlers ("TD") looked for longer at the social stimulus. Toddlers with developmental delay ("DD") also showed the typical pattern of a social preference. This study is a clear example of how children with autism are simply showing a difference in their patterns of interest. Looking at a social stimulus may be the typical pattern of attention, but not conforming to this pattern is not necessarily a sign of being worse or impaired, since it is simply reflecting that toddlers with autism allocate their attention to different aspects of the environment. See Fig. 111.3.

Neuroethics of Neurodiversity

So what are the benefits of thinking in terms of neurodiversity? The most obvious benefit is in terms of inclusion and acceptance. Instead of those with a diagnosis feeling in some way inferior or excluded, the notion of neurodiversity breaks down divisions between those with and without a diagnosis by acknowledging that people

are simply "differently wired" and that it is misplaced to think of some people's wiring as "normal." When I was a child, "left handers" were still regarded as abnormal and coerced to write with their right hand as the only right way (no pun intended). I am an example of this kind of educational antidiversity. A second ethical implication is in terms of human rights, where those with autism, for example, have applied the same human rights framework to those with a disability as might be applied to any other minority group (e.g., based on ethnicity). The positive effect of this has been for the majority "culture" to think of how the environment can be adapted to avoid any risk of discrimination. Just as traffic lights need to be designed to be heard as well as seen, to improve their access to the blind as well as deaf pedestrians, we can imaginatively consider all parts of our environment, both social and physical, to make it equally accessible to a diverse range of neurologies. A third ethical implication is that because someone is neurologically different, this does not mean they need a treatment or a cure. They may need support (people with autism are a good case in point who need support for their social disability), but their difference includes their excellent attention to detail (Jolliffe and Baron-Cohen 1997) and treating them for their autism might risk them losing such superior skills.

However, we have to consider the limits of the notion of neurodiversity. One is that not all kinds of neural wiring are equally good, since some actually cause "disease." Examples would be Parkinson's disorder, epilepsy, or dementia. These cause unequivocal impairment, where the ethical option is treatment if this is available, to improve the quality of a person's life. Uncontroversial "targets" for treatment in some people with autism include certain "comorbid" symptoms that are sometimes present in autism such as epilepsy, gastrointestinal pain, self-injury, and even severe learning difficulties. Even aptitudes such as social skills and communication are reasonable targets for treatment and intervention. As with all interventions, the priority has to be ensuring the benefits are not outweighed by any unwanted side effects. In the case of autism, the goal should be to identify interventions that target the areas of clear disability, whilst leaving the areas of difference to blossom and reach their full potential. How to assess functioning and flourishing in people who are neurologically different and where to draw the line between disability and difference are questions that professionals need to continuously revisit (Fenton and Krahn 2007; Jaarsma and Welin 2011). We need to embrace the notion of neurodiversity, but without applying it unthinkingly to all forms of neurological difference.

Section XXIII

Weaponization of Neuroscience

Weaponization of Neuroscience

112

Gerald Walther

Contents

Abstract

This introductory chapter to the section on the "Weaponization of Neuroscience" provides a short overview of the developments in biological disarmament since the beginning of the twentieth century. It starts with an account of the problems at the Fifth Review Conference of the Biological and Toxin Weapons Convention to establish a verification regime and how the Convention subsequently shifted its focus from state to non-state actors in terms of preventing the development of biological weapons. As part of this reorientation, the issue of the potential misuse of benign scientific research was raised, which was coined "dual-use biosecurity" or the "dual-use dilemma" in the following debates. While the international security community was initially only worried about the misuse of neuroscience by malign non-state actors, the disarmament community has expanded the topic to include the use of scientific research by state military as well.

The five chapters in this section discuss the following: Is neuroscience research of interest to the military? Does international law regulate neuroscience? What is the level of awareness and education of neuroscientists on the topic of dual use? How can the neuroscience community work towards protecting their research from misuse? What can neuroethics do?

Biological Disarmament in the Twentieth Century and the Origins of Dual-Use Bioethics

It is probably not farfetched to argue that the events of 9/11 had a profound impact on international politics. However, in the shadows of 9/11, the anthrax attacks that followed proved to be equally important to the security community and particularly to those interested in biological disarmament. Just prior to 9/11, the Biological and Toxin Weapons Convention (BTWC) suffered a significant setback in strengthening its ability to ensure a biological weapon-free world. The BTWC, albeit already established in 1972, lacks a regime that oversees whether signatory states actually comply with the regulations set out in the Convention, which is primarily to prohibit any work that could be used for the production, stockpiling, or delivery of biological weapons. In 2001, at the fifth review conference, a proposal had been put forward by the then Chair Tibor Tóth to remedy this lack. However, the USA eventually refused their support for this proposal and questioned the utility of trying to come up with a verification regime altogether. In this political disaster, 9/11 and the anthrax letters fell. As part of a way forward for the BTWC, the topic was opened up of how likely biological research could be misused for malign purposes, i.e., bioterrorism, and what could be done to decrease the prospect of it. The label for this discussion was "dual-use biosecurity."

The discussion was heavily influenced by the work of the so-called Fink Committee, or in full the "Committee on Research Standards and Practices to Prevent the Destructive Application of Biotechnology," which worked between April 2002 and January 2003 to produce a report published in 2004 by the US National Academy of Science. The Fink Committee identified two issues. First, domestic and international legislation ensures the physical protection of laboratory workers and the environment from harmful or novel biological agents. However, these regulations do not address the issue of how research could be protected from being abused and misused by malign actors. There is also no method or process on how to weigh the potential dangers of misuse against the beneficial aspects of research. The Fink Committee proposed to address this issue by engaging the scientific community in a dialogue as well as to establish oversight committees that evaluate scientific work on a danger vs. benefit scale. In the committee's view, scientists have a "moral duty to avoid contributing to the advancement of biowarfare and bioterrorism" (NRC 2004, p. 112). While this debate on the role and responsibility of scientists was going on within the international security community, i.e., primarily within the BTWC, both scientists and bioethicists were largely silent on the issue. Of course there were some initial reactions, for example, several editors of major biology journal, who had been consulted by or had been members of the Fink Committee, issued a joint statement in 2003, where they promised to take into consideration biosecurity and biodefense concerns when publishing a paper. Nevertheless, as Minehata and Walther describe in ▶ Chap. 113, "Biosecurity Education and Awareness in Neuroscience" of this section, this discussion of the duty of scientists did not extend or involve the majority of the scientific community. Equally, it took until 2009 for Dando to note that the

bioethicists had finally entered the dual-use debate (Dando 2009). This claim was based on three articles (Kuhlau et al. 2008; Ehni 2008; Miller and Selgelid 2008) that discussed the moral responsibility of scientists and what they could be expected to do in order to reduce security concerns about their work. Except for these three articles though, dual-use bioethics has not attracted much further attention from bioethicists. The debate is thus largely dominated by the security community and has yet to reach the widespread attention of practicing scientists or bioethicists. However, in 2011, the case of the H5N1 research has shown how contentious the issue may become as the security community is trying to change legislation and increase both oversight and regulation of scientific work. In the H5N1 case, a mammalian-transmissible H5N1 influenza was created, which raised the question of whether this research could have been considered as offensive biological weapons research and if the risks associated with publishing the research outweigh any potential benefits (Novossiolova et al. 2012). Opinions on this issue were quite divided between the security and science community, and even internally there was no consistency, so this topic might spark further debates in the future.

Section Overview

The first chapter in this section by Minehata and Walther highlights the current awareness of the dual-use topic among scientists and particularly neuroscientists. They advocate the use of education to help the science community deal with the security implications of their work, which includes the use of research by the military, before it becomes a political issue (Minehata and Walther). After all, it cannot be in the interest of the scientific community to have unaided lawmakers start to regulate science. However, as the chapter points out, current awareness of this issue is very limited among scientists, and it will presumably take time for this issue to become a topic of debate. Education programs that address this issue are very limited at the moment. Only the University of Bradford in the UK has a training module that specifically teaches the issue of dual-use bioethics to practicing scientists (http://www.brad.ac.uk/bioethics/). While the project has been running successfully since 2010, the number of its graduates is just over 100 so the impact is as yet limited. In the neurosciences, a series of workshops have been held at the University of Manchester and the University of Bradford in 2012 and 2013 to develop an ethics course for neuroscientists, which will include a component on dual-use bioethics as well (http://www.lab.ls.manchester.ac.uk/neuroethicseducation/). Within neuroethics, the issue of the relationship between the military, national security, and neuroscience has been discussed in a target article and several open peer commentaries in Volume 1, Issue 2, of the American Journal of Bioethics Neuroscience (Marks 2010) and in a booklet by The Royal Society (2012). It has also featured as a panel on “Neuroscience, National Security, and Society” at the 2011 meeting of the International Neuroethics Society meeting.

As discussed by panelist James Giordano, one of the problems with discussing the potential malign uses or misapplications of neuroscience is a lack of pragmatic

consideration of what is actually feasible (http://www.neuroethicssociety.org/2011-meeting-archive). Popular science fiction, for example, the idea of a "Manchurian Candidate," may cloud what can actually be accomplished and influence public opinion and understanding in excess of the facts. In ▶ Chap. 114, "Neuroscience Advances and Future Warfare" in this section, Dando takes a look at history of neuroscience and the military with regard to the development of lethal nerve gases. From there, he discusses the potential of misuse or military use of contemporary neuroscience developments and neurotechnologies. The primary argument is that the emphasis on misuse, e.g., bioterrorism, is misguided and that in the sort of asymmetric warfare in the coming decades, a militarization of the life sciences is more likely and needs to be monitored. As examples of current technology, Dando looks at transcranial magnetic stimulation and brain-computer interfaces and their implications for information processing and autonomic weapons systems and how these will pose challenges to our understanding of morality and international law.

The question of the interaction between international law and the militarization of neuroscience is taken up specifically by Jefferson in ▶ Chap. 115, "International Legal Restraints on Chemical and Biological Weapons" of this section. She discusses international conventions such as the BTWC and the Chemical Weapons Convention with a specific focus on how they regulate incapacitants, which act on the nervous systems and therefore could be considered neuroweapons. Even though Jefferson concludes that international conventions cover neuroweapons such as incapacitants, she agrees with Dando that education of neuroscientists is necessary to raise awareness in order to reduce the likelihood that neuroscience will be militarized.

However, as has been shown in the Minehata and Walther chapter, despite efforts to promote ethics education from State Parties, there has been little progress made thus far. Novossiolova takes up this challenge and discusses how biosecurity needs to be understood in the context of changing norms and values within an epistemic community.

The final chapter of the section shifts the focus by analyzing how neuroscientific insights could have an impact on international law. Walther challenges current international humanitarian law and its focus on preventing physical harm to civilians and improving the security of combatants. Based on a review of how fear, anxiety, and stress impact neurophysiology and can cause long-term or permanent damage to the individual, he argues that recent military strategies such as "shock and awe," as used in the 2003 Iraqi invasion, as well as military interest in "fear creation" may lead to more psychophysical harm. He concludes that neuroethicists should use their understanding of neuroscience to inform and change humanitarian law in the future.

Conclusion

The militarization of neuroscience is not a novel issue. The twentieth century saw several neuroweapons in deployment, starting with the development and use of lethal nerve gases in the World Wars. However, with the surge in our understanding

of the brain and the nervous system since the late twentieth century, the potential for use by malign actors as well as the military has increased considerably. And it is not only the fear of science-fiction dystopias that the neuroethics and neuroscience community should actually be concerned about. Current neurotechnologies already offer possibilities of misuse, and these are more readily accessible than ever before. The public needs to be assured that neuroscience does not open a Pandora's box but that the implications for our open civil society are not threatened by these developments. This section will argue that education and awareness-raising are two tools to allow neuroscientists to understand their impact on society as well as enable them to evaluate the risks of their research. These questions might be best served by a conscious deliberation by individual scientists rather than a sole reliance on Ethics Review Boards.

Biosecurity Education and Awareness in Neuroscience 113

Masamichi Minehata and Gerald Walther

Contents

Abstract

This first content chapter of the section starts with a short historical overview of the military interest in neuroscience research. Based on this account, it asks the question of how neuroscience has responded to the ethical issues that have emerged as part of these research activities. An analysis of current ethical training shows that such a debate has been underdeveloped and that the question of dual-use within ethics education of neuroscientists is very limited. Based on these findings the chapter explores the relationship between the security community, specifically, the Biological and Toxin Weapons Convention, and how neuroethicists could help the Convention in addressing the lack of awareness within the neuroscience community of the militarization and dual-use of their research and technologies.

Introduction: The Historical Dimension of Military Interest in Neuroscience

While the military community has become very interested in recent advances in neuroscience research, this awareness of the potential of neuroscience for warfare is far from novel. Already in the early stages of modern neuroscience during and after World War II, research into functional neuroanatomy was of keen interest to the military. For example, Jose Delgado's work in the 1950s and 1960s, which was funded by two agencies within the Department of Defense (Snyder 2009), including the Office of Naval Research (Horgan 2005), attracted attention because of his experiment in 1964 in Spain where he was able to stop the charge of a "black bull," a breed of bulls used for bullfighting, toward him by flipping a switch that activated an electrode implanted in the brain of the bull. While it is inconclusive as to whether Delgado was able to reduce the aggression or simply inhibited the movement of the bull in this specific experiment, which nevertheless received considerable attention by the media, the *Time Magazine* has already reported in 1953 that Delgado had been able to reduce aggression in macaque monkeys (Snyder 2009).

In addition to this interest in the open scientific community, the military's own, top secret program "MK-ULTRA" also used neuroscientific and psychological insights and techniques for a variety of purposes. Unfortunately, nearly all documents of its existence have been erased. The program was established in the early 1950s and continued until 1973 and used a variety of tools, such as the use of psychopharmacological agents, e.g. LSD, or psychological methods, e.g. hypnosis, to alter the state of minds of soldiers for beneficial, i.e. producing "supersoldiers," or malign purposes, i.e. controlling behavior or improving torture techniques (Streatfeild 2006). In 1965, seven psychologists delivered a classified paper to the Pentagon titled "Phenomena Applicable to the Development of Psychological Weapons," which outlined "how arms makers could enhance the psychological effect of new weapons, how fear could be promoted, how perceptions could be altered, how the stress of combat could be increased, and how the psychological differences among racial groups could be exploited" (Moreno 2012, p. 98).

Besides this interest in functional neuroscience, pharmacological agents to kill or demobilize the enemy have of course already been used in World War II, where Germany used the nerve gas VX. While, as discussed by Jefferson in ▶ Chap. 115, "International Legal Restraints on Chemical and Biological Weapons," the *Biological and Toxin Weapons Convention* (*BTWC*) prohibits the use of biological weapons, some agents acting on the nervous system may only be covered by the *Chemical Weapons Convention* (*CWC*), which allows the use of riot control agents, which mainly affect the nervous system, for domestic law enforcement purposes. In 2002, the Russian police used a nerve gas to incapacitate terrorists that held several hundred people as hostages in a Moscow theater. The outcome of the use of the incapacitant was 117 deaths as well as permanent damage to others (Schliermeier 2002).

Given this long history in the work of neuroscientists, it may be presumed that the community has developed a code of conduct for their research behavior or at least discussed the implications of their research for society and the military. The next section will analyze if this hypothesis can be validated.

Ethical Training in Neuroscience is Underdeveloped

In a commentary in *Science* in 2009, Barbara Sahakian and Sharon Morein-Zamir urged the neuroscientific community to introduce ethical training to neuroscience curricula because advances in neuroscience will have important ramifications for "*education*, treatment, and the law" (Sahakian and Morein-Zamir 2009). In their informal survey among 20 major research-intensive universities in the UK, they found that little formal ethical training is given to students (Sahakian and Morein-Zamir 2009). In Canada on the other hand, a telephone survey conducted in 2010 provided an opposite picture (Lombera et al. 2010). In order to verify if there is a possible discrepancy between the educational systems, Walther (2012) conducted a survey in several countries – Australia, Canada, Germany, the UK, and the USA – of both undergraduate and postgraduate neuroscience courses.

The survey first looked at information available at department web pages about ethical training, which was then supplemented by a questionnaire sent to the course administrators. Combining both types of data showed that 52 % of all courses had some form, i.e. formal or informal, of ethics training compared to 80 % when just taking into consideration the questionnaire responses. Formal training was given in 63 % and 60 %, respectively, of the courses that had ethical training. In terms of a possible variation between countries in terms of ethical training, the survey concluded that all countries had similar results. The only exception was the UK, specifically with regard to the question if formal training is given in the courses. All ethical training provided in the UK was delivered in informal sessions. Walther argues that a form of "mainstreaming" has taken place in the UK, which is a term used within business ethics education, where ethical issues are discussed in an ad hoc manner rather than having an exclusive course on the issue. The idea behind it is to bridge the gap between training and practice. Of course, explaining that ethical training has been embedded within all of the modules of a course may simply be a more sophisticated way of saying that ethics is actually not being taught.

When asked about the issues that are addressed in the ethical training, Walther reports that the most common issues were "human and animal use in research," "research misconduct," "treatment of data," "authorship and allocation of credit," and "the researcher in society." While the first four may be considered standard issues within the ethics of science, the last entry of the role of the researcher in society might constitute a discussion of the implications of research on society, which would cover issues of militarization of research and the potential for it to be misused by malign actors. However, the topic rather stresses the role that a scientist has as an expert in a debate and how scientists can reconcile their professional duty to be objective with their subjective wishes, convictions, and beliefs. Indeed, in the

survey the phrase dual-use was only mentioned in 6 % of all of the courses in the sample.

Indeed, proposed solutions to the topic of misuse of research by malign actors as discussed in the *BTWC* arena, where the focus is on malign actors such as terrorists and not misuse by the military of States Parties, may run counter to prevailing practices of scientific publishing. For example, in order to reduce the likelihood that research can be misused by these malign non-state actors, it has been suggested to reduce the amount of information available within publications in order to make it more difficult to replicate the experiments and, for example, be able to replicate a particular pathogen or modify existing ones to make them more virulent. However, the *Journal of Neuroscience* published by the Society for Neuroscience clearly states in its "guidelines for authors of scientific communications" that they are required to make all "unique and propagatable" material accessible to anyone who asks for them under article 1.12 (Society for Neuroscience 2012). The only reservations are where commercial interests are at stake. These rules are part of the scientific canon of the freedom of scientific inquiry and the collegial nature of a communal inquiry for scientific explanations and the generation of knowledge. Thus, any interference with the freedom to publish will be seen as an attack on the values of the community that have yielded remarkable success in modern times.

Having considered the lack of awareness, *education*, and policy development to promote awareness raising of neuroscientists about dual-use issues, it might prove useful to inquire about the state of education in the wider field of the life science. The following sections expand an analytical scope to the current state of education of *dual-use* issues in the life sciences.

Necessity for Awareness Raising of Life Scientists

A major challenge for today's international community has been to find effective ways to raise awareness among life scientists about their social responsibility regarding the potential for the destructive use of the life science research in which they are engaged. The life sciences differ from nuclear science developments in that they are conducted around the world in commercial and academic laboratories rather than those belonging to national governments (National Research Council 2006). In addition to this wider scale of practice, the actual speed of scientific advancement and resulting security implications are "possibly too fast for any State, organization or individual to cover alone" (Millet 2010, p. 29). Moreover, there are critical ambiguities surrounding the boundary between defensive and offensive biological programs which can be used to blur issues of legality (under the *BTWC* that the development of all biological weapons is illegal, as is their production, acquisition, transfer, retention, stockpiling, and use). Finally, in order to address the concerns of scientists, approaches aiming to promote a culture of biosecurity-based social responsibility need to be mindful to "ensure a focus on the highest-risk research and avoid unnecessary restrictions or censorship" over scientific freedom (Smith et al. 2010, p. 137).

Accordingly, there is a need for better collaboration between scientific communities and policy-makers. For this very reason, there is also a need for *education* specifically designed to better inform scientists' and policy-makers' understanding of how the potential for the misuse of the life sciences and related technologies can be recognized and prevented. In this chapter, such efforts to develop a web of preventive policies are broadly envisaged as *biosecurity* (Feaks et al. 2007). It is suggested that such biosecurity education should incorporate themes such as, inter alia, the potential for dual-use risks in contemporary life sciences; the responsible conduct of research and ethical approaches among life scientists; the history of biological warfare programs and biological terrorism; the role of international prohibition regimes and their national implementation (such as the BTWC); the intersection of public health and national security; and the building of an effective set of preventative policies to ensure the security of benign developments in the life sciences.

Increased International Attention and Remaining Problems

The necessity of awareness raising among life scientists about dual-use issues has been underlined by governments and professional communities in science, public health, security, and ethics (Miller and Selgelid 2007; Gorski and Spier 2010). These include the InterAcademy Panel (IAP) (Inter-Academy Panel 2005; Nature 2003), the World Health Organization [WHO] (2007), the Organization for Economic Cooperation and Development [OECD] (2007), and the BTWC (2008). However, against such growing international attention towards *biosecurity education*, the lack of awareness of individual scientists across the globe has been clearly demonstrated (Dando and Rappert 2005; Rappert et al. 2006). Further to this, the limited availability of biosecurity tutoring at the university level has been illustrated by a series of international surveys investigating the current state of biosecurity-related degree courses in the United States (National Research Council and American Association for the Advancement of Science 2009), Europe (Mancini and Revill 2008), Japan (Minehata and Shinomiya 2010), Israel (Freedman 2010), and the Asia-Pacific region (Minehata 2010). In the case of Japan, for example, it was noted that a range of difficulties were faced by university lecturers in introducing appropriate teaching due to:

- An absence of space in existing curricula
- An absence of time and resources available to develop new curricula
- An absence of expertise and available literature on biosecurity education
- General doubt and scepticism about the need for biosecurity education on the part of educators and scientists (Minehata and Shinomiya 2010)

Despite these commonly experienced obstacles, the surveys indicated the possibility of promoting biosecurity education by utilizing already-implemented ethics education processes. We found that a large number of universities surveyed already have educational modules focusing on ethics. Therefore, it has been suggested an expansion of the scope of traditional ethics education by integrating the concept

of dual-use biosecurity as part of the *education* in social responsibility already offered to life scientists (National Research Council and American Association for the Advancement of Science 2009; Revill et al. 2009).

What Is Needed?

A good strategy is needed to deal with the range of obstacles by showing that biosecurity education may be implemented and that it need not be expensive, time-consuming, or onerous in terms of workload. What kind of educational material can be of use in the absence of widespread expertise and available literature on *biosecurity education*? One answer is to place open-source teaching materials online, via the Internet. There are a number of benefits to this approach. Firstly, it is important to recognize that there is no "one-size-fits-all" answer to biosecurity education. Secondly, there are significant differences in priorities between academic institutions, national and regional needs, and also variations derived from differing sociocultural backgrounds. Because of these distinctions, online educational resources are useful, as they can be modified and tailored by users in order to fit the specific teaching modes and needs in various local educational contexts. Further, they ease pressures on time spent in planning and preparing material, overcome financial constraints on the development of biosecurity curricula, and provide the expertise required for efficient and effective assimilation of such material (Dando 2008). In addition, tutors are free to choose what to include in sessions and at what level to "pitch" their teaching, depending on the educational level and technological perspectives of the audience.

Following on from the use of this type of educational resource, the next stage in promoting biosecurity education is to build education capacity through the implementation of similar modules in different academic contexts and institutions. This will disseminate knowledge and understanding more broadly and is likely to engage a wider range of students, educators, and scientists as it is implemented.

Who Should Be Involved?

At the Meeting of Experts of the *BTWC* in 2008 during the discussion on education, States Parties addressed this view by noting that target audience of dual-use education should include medical institutions, scientific organizations, professional institutions, companies, policy-makers' administrators, and universities and authors, editors, and publishers (Japan in consultation with JACKSNNZ 2008, p. 2; Netherlands 2008, p. 6). Indeed, the significance of raising awareness about the ethical responsibility of scientists in preventing the misuse of the life sciences, and to preserve scientific autonomy, has been widely discussed in literature (Atlas and Dando 2006; Kuhlau et al. 2008; Selgelid 2007; Somerville and Atlas 2005). It is

necessary that scientists assume their social responsibility for any dual-use consequence of their research. This is because scientists are at the forefront of scientific understanding and are thus best placed to envisage the consequences of their research. This indicates their primary responsibility in extending the culture to "do no harm" into the area of dual-use against humans, animals, and plants. They are the primary actors who can "help ensure a focus on the highest risk research and avoid unnecessary restrictions or censorship" (Smith et al. 2010, p. 137).

At the same time, nonscientists have the ethical responsibility of doing no harm against the freedom of scientific research. Scientists are creating innovative knowledge with a view to making social benefits in terms of medicine, the environment, and socioeconomic benefits which other social actors can enjoy. The freedom of scientific inquiry, as well as the freedom to share knowledge including the form of publications, is a fundamental human right. Even if a possibility for the misuse of science exists, security regulation over peacefully designed scientific research requires careful dialogue between scientists and nonscientists.

Awareness about dual-use issues is not only the matter of ethics of scientists, but it is more about the practical interest of professional development, such as publication or funding of scientific research. For example, the combination of voluntary awareness raising of scientists about dual-use issues by scientific community, national legislation on *biosecurity* and biosafety measures, and oversight of scientific research was underlined by the "Statement on the Consideration of Biodefence and Biosecurity" signed by the editors of some 30 privileged scientific journals, including *Science*, *Nature*, and *Cell*, in 2003 (Nature 2003) as well as by the "Statement on Biosecurity" of the InterAcademy Panel which was endorsed by national science academies of more than 60 states in 2005 (IAP 2005). In 2008, the US "National Science Advisory Board for Biosecurity" (NSABB) introduced a strategic plan "to provide recommendations on developing programs of outreach and education on dual-use research issues for all scientists and laboratory workers at federally-funded institutions."

Fukushi (2012) illustrated that there are potential intervention points to promote awareness raising of neuroscientists about *dual-use* issues. Regarding the role of journal editors, "*Neuroethics*," "*Journal of Cognitive Neuroscience: Neuroethics Section*," and the "*American Journal of Bioethics: Neuroscience*" can be great places to address issues alongside the journals which recognize the issue with the "Statement on the Consideration of Biodefence and Biosecurity" mentioned above. Professional societies also have great opportunities to address dual-use issues through their annual conferences or training programs; for example, the Wellcome Trust in the UK organized the Summer School on Neuroscience, Ethics and Society 2005 and the European Neuroscience and Society Network organized training programs between 2007 and 2012, including the "Interdisciplinary NeuroSchool" in 2008. Then, the growing number of neuroethics center could facilitate discussion within the community and engage with the security as well as the neuroscience community.

How Can It Be Internationally Promoted?

It has been reported that the implementation of such resources at different academic institutions has been taking place internationally although the number is limited (National Research Council 2010). For the next step, what is really needed to mitigate against a slow advance in the spread and uptake of international biosecurity education is the development of an international network to share emerging best practice.[1] Currently, international efforts to advance education on dual-use issues have only been developed by individual academic institutions, i.e. efforts to date have been mainly "bottom-up." In order to further advance the agenda, "top-down" efforts to provide a structural change in the education culture of the life sciences are also needed. For this purpose, the high-level engagement of governments with coordinated policy decisions is essential.

The Seventh Review Conference of the *BTWC* in December 2011 demonstrated a possible strategic approach.[2] This became a major opportunity for the international community to advance the topic of education as a high priority. Firstly, efforts need to concentrate on the facilitation of the implementation of biosecurity education at different academic institutions. Secondly, efforts are needed to encourage the formalization of further international frameworks to discuss and promote the enhancement of dual-use and biosecurity awareness among scientists. Rappert (2010) has suggested that such formalization may include:

- The establishment of international state coordinators and/or regional coordinators
- The organization of continued international workshops to share best practice
- Provisions of bilateral and multilateral assistance
- Greater incorporation of civil society organizations into the BTWC
- Yearly reporting of activities

By engaging with biosecurity education, neuroscientists can play a significant part in the formation of the next generation of scientists in whose hands the future well-being of society may well be assured.

In result of the Seventh Review Conference, the *BTWC* has set out annual meeting process including Standing Agenda Item – annual agenda item – towards the Eighth Review Conference in 2016. Professional societies, journal editors, and universities in neuroethics field, which were identified in the previous section, should further collaborate with their own national focal points of the BTWC in order to help facilitate possible policy decisions at the international level. In other words there are many opportunities for neuroscientists and neuroethicists to play international roles to promote awareness raising.

[2]Since 1980, Review Conferences have taken place once every 5 years and the next Review Conference will take place in December 2011.

Conclusions and Future Directions

This chapter identified the pervasive lack of awareness and the lack of education of dual-use topics for neuroscientists. The chapter comparatively analyzed how such deficiency could be distinct from the current state of biosecurity education in the broader context of the life sciences. The analysis provided a nearly identical picture in life science fields. However, there has been a series of achievements to develop a comprehensive approach to promote education for life scientists. The term comprehensiveness here characterizes the following points. Efforts are needed to develop a diverse range of education material, training program, and networking. It also requires the engagement of all stakeholders, including science communities, funding agencies, university accreditation bodies, journal editors, export control branches, public health sectors, and security communities. Moreover, actions are necessary to be taken at all levels to change the culture of responsible conduct from the individual level to the international policy world combining bottom-up and top-down efforts. Such comprehensiveness is instrumental to help mitigate the current lack of awareness of dual-use issues in neuroscience community. Indeed, the chapter indicated that there is certain possibility to achieve this endeavor.

Neuroscience Advances and Future Warfare

114

Malcolm Dando

Contents

Abstract

This paper begins by recalling that advances in neuroscience were used for hostile purposes, for example, in the development of lethal nerve gasses, in the last century, and it is argued that in the kinds of asymmetric warfare likely to characterize coming decades, such advances could again be utilized to develop novel weapons. The paper then suggests that the idea that the problem is that bioterrorists will immediately be able to design and use advanced biological and chemical weapons is misguided and that the real question is how the wholesale militarization of the life sciences can be prevented. It is in that context that the paper examines the dangers of misuse that could arise from some current developments in neuroscience. It is argued, for example, that benignly intended civil work on transcranial magnetic stimulation (TMS) and brain-computer interfaces (BCIs) has to be understood in the context of modern military interests in data collection and analysis from drones and the probable development of

autonomously acting systems. The difficulties that such novel weapon-related developments will cause for our present understanding of morality and international law are reviewed, and finally, it is suggested that neuroscientists trying to adjust their concepts of responsible conduct in these circumstances will need the help of neuroethicists.

Introduction

In 2006 the *Journal of the History of the Neurosciences* carried a long paper (Schmaltz 2006) titled "Neurosciences and Research on Chemical Weapons of Mass Destruction in Nazi Germany." The paper gives a detailed account, based on the most recently available documents, of how work on potential pesticides led to the discovery of tabun, sarin, and eventually Soman – the first of the lethal nerve gasses – in the context of the force-on-force mechanized warfare of that time.

What is striking about this account, as is clear from the title, is the way in which basic neuroscience research was "enmeshed" in applied offensive and defensive chemical warfare research. The primary effects of the nerve agents, for example, "were originally identified at a branch laboratory of the Military Medical Academy, by Gremels, the Director of the Pharmacological Institute of the University of Marburgh," and "The methods and models applied at the KWI [Kaiser Wilhelm Institute] for Medical Research, originally developed for research on vitamins and enzymes, were an important condition for the1944 discovery of the nerve agent Soman" which was at that time the most potent inhibitor of cholinesterase and thus the most deadly nerve agent.

Such historical research should alert us to the need to be careful that the very rapid advances in neuroscience being made in our time are not similarly used for warfare and other hostile purposes. In that regard, we have to acknowledge that in the new kinds of asymmetric warfare that will characterize coming decades (Development, Concepts and Doctrine Centre 2010):

> The CBRN [Chemical, Biological, Radiological, Nuclear] threat from state and non-state actors is likely to increase, facilitated by lowering of some entry barriers, dual-purpose industrial facilities and the proliferation of technical knowledge and expertise...

Moreover, this forecast continues: "Terrorist attacks using chemical, biological and radiological weapons are likely, as are mass-casualty attacks using novel methods." It is worth noting that in this estimate the word "likely" is stated to indicate a 60–90 % probability.

We have, of course, become familiar, since the turn of the century, with the fact that the genomics revolution and neuroimaging technologies will transform our understanding of the function of neurotransmitters and neuroreceptors in critical brain circuits (Andreasen 2001) and that this knowledge might be misused. What is clear from more recent accounts of the possible advances in neuroscience is the importance of information technology more generally in understanding and

manipulating brain functions (Horstman 2010), and it cannot be ignored that information technology is becoming more and more important in the operations of military forces in many countries.

The aim of this paper is not to attempt a survey of all the kinds of neuroscience that could perhaps be misused for hostile purposes such as the epigenetic influences of the social environment (Champagne and Curley 2011), but rather, by discussing some more obvious examples, to illustrate why considerations of the darker side of possible advances and applications are important for neuroscientists and, by implication, neuroethicists, to consider. It should also be noted that the concentration here is on uses in acts of warfare rather than in other possible misuses such as terror, interrogation, or torture.

Framing the Question

In the report of the Commission on the Prevention of WMD Proliferation and Terrorism in 2008, US Senator Bob Graham and his colleagues concluded that (Commission on Prevention of WMD Proliferation and Terrorism 2008):

> . . .it is more likely than not that a weapon of mass destruction will be used in a terrorist attack somewhere in the world by the end of 2013.

Immediately following that statement, the Commission added:

> The Commission further believes that terrorists are more likely to be able to obtain and use a biological weapon than a nuclear weapon. . .

In short, a biological weapon would be used, as a weapon of mass destruction by terrorists by the end of 2013.

That has always seemed a wildly exaggerated threat assessment to me. It has been clear for at least 50 years that biological weapons could be used to cause mass casualties (Wheelis et al. 2006), but weaponization of biological agents is clearly difficult unless a State decides to embark on an offensive biological weapons program. Indeed, the 2001 anthrax letter attacks in the USA used material developed in the 25-year-long US offensive program, and that is probably the only such attack that has taken place since the Second World War. The idea that terrorists would be easily able to utilize advanced techniques of modern biology to produce and use new types of dangerous biological weapons without access to the resources of a State seems even more farfetched as the tacit knowledge required would not likely be available to nonspecialists just reading the scientific literature (Vogel 2008). These facts strongly suggest that there is something amiss with the overconcentration on the threat of bioterrorism that we have witnessed in the last 10–15 years.

A further worry arises when the overconcentration on bioterrorism is linked uncritically to the threat of modern biological research being of "dual-use concern" and therefore needing new forms of governmental oversight

(Gottron and Shea 2012). If the discussion in 2005 over the publication of the sequencing and synthesis of the genome of Spanish influenza did not suggest that in a vanishing small number of instances would consensus be reached that the risks would outweigh the benefits of publication, surely the recent debate on the creation of mammalian-transmissible H5N1 influenza should have given pause for thought (Novossiolova et al. 2012). Do we really need to have a vast oversight system when even the prevention of the publication of a route to a "perfect bioweapon" is not thought necessary?

One possible response to this line of argument is to reject the whole idea of being concerned about the hostile misuse of the modern life sciences. As one commentary on the H5N1 debate suggested (Trevan 2012):

> The best strategy to stop biological attacks is to make biological weapons unattractive by making preparations and response so effective that the consequences are no worse than a train wreck. Increases understanding of transmissibility and pathogenicity will enable countries to identify threats earlier, develop better vaccines, produce them more quickly and develop broad-spectrum defences to diseases. . .

That again seems an unrealistic approach to me, in part, because I find it difficult to imagine States devoting sufficient resources to achieving such ends.

More fundamentally, however, I think it is a wildly optimistic forecast of what is likely to happen if a State-level offensive biological arms race is allowed to develop in coming decades on the back of the revolution in modern biology and its increasing industrial application. A much better way to frame our question and to answer it properly is not in terms of potential bioterrorism and response, but to see that as a small part of a much larger future danger. That danger was set out very clearly by Professor Mathew Meselson of Harvard University in 2000 (Meselson 2000):

> . . .During the century ahead, as our ability to modify fundamental life processes continues its rapid advance, we will be able not only to devise additional ways to destroy life but will also become able to manipulate it - including the processes of cognition, development, reproduction, and inheritance. . .

Meselson then pointed out the consequences if human society allowed this to happen:

> . . .A world in which these capabilities are widely employed for hostile purposes would be a world in which the very nature of conflict had radically changed. Therein could lie unprecedented opportunities for violence, coercion, repression, or subjugation. . .

Moreover, these capabilities would be widespread:

> . . .Unlike the technologies of conventional or even nuclear weapons, biotechnology has the potential to place mass destructive capabilities in a multitude of hands and, in coming decades, to reach deeply into what we are and how we regard ourselves. It should be evident that any intensive exploitation of biotechnology for hostile purposes could take humanity down a particularly undesirable path.

Therefore, while I believe that bioterrorism is given too much attention at the present time, I would certainly not discount it in a future in which the use of

modern biology for hostile purposes has become a commonplace among States. A major danger at the present time is precisely in regard to the activities of some States which, as discussed in the Royal Society Brain Waves Module 3 report on *Neuroscience, conflict and security* (Royal Society 2012), appear to be endangering the prohibition regime because of their interest in new forms of incapacitating chemical agents derived from ongoing advances in neuroscience.

An idea of what might well happen in a prolonged arms race in biological weapons was set out by three US analysts in 2003 (Petro et al. 2003). They suggested that there would likely be three overlapping phase. The first would involve the use of traditional agents such as anthrax, but as there are only a limited number of such agents, the defense would eventually be able to catch up. Then the offense would move to modify such agents by the use of genetic engineering, but, again, as there are only a limited number of such modifications possible, in theory the defense could again catch up. However, as our understanding of living systems continues to improve, there would be many more targets that could be attacked in an increasing number of diverse ways through the use of new advanced biological agents. In such a situation, I find it difficult to see anything other than a prolonged period of offensive superiority even if huge resources were to be thrown into biodefense.

Of course, in such an environment, it would be difficult to ensure that others understood that biodefense was not, in fact, part of an offensive program. Additionally, efforts to "enhance" military forces, as has been envisioned in some recent literature, might, again, be perceived as degradation of another State's "normal" forces. Moreover, benignly intended uses of modern technology within the military could have perverse effects by what has been termed "reverse dual use" within civil society (Marchant and Gulley 2010). Indeed it is necessary to emphasize that the problem is the potential for multiple means of misuse over coming decades not of terrorists taking up advanced biotechnology to create weapons of mass destruction now. I will not pursue these complexities further here except to say that we have to be aware that in such muddy waters, there can be subtle marketing of new weapons systems – such as the misappropriation of humanitarian arguments for new "nonlethal" weapons (Tafolla et al. 2012) in the same way as new chemical weapons have been justified in the past. This is particularly important because at the moment neuroscientists, like most practicing life scientists, have very little awareness of the potential for their benignly intended work to be misused for hostile purposes (Australia et al. 2011).

Novel Neurotechnologies

Recently some neuroethicists have begun to analyze the problem of dual use. In the UK, for example, the Nuffield Council on Bioethics has decided to investigate three novel brain technology areas: brain-computer interfaces, neurostimulation, and neural stem cell therapy. In its *Consultation Paper* of March 2012 (Nuffield Council

on Bioethics 2012), the council clearly notes that there are possible concerns in regard to the military/hostile uses of brain-computer interface technologies (BCIs) and of transcranial magnetic stimulation (TMS).

TMS

The potential misuse of TMS has been examined recently in a collection of essays on *Innovation, Dual Use and Security: Managing Risks of Emerging Biological and Chemical Technologies* (Tucker 2012). The authors of the essays were asked to examine the present state and future trajectories of a series of different technologies, then to assess the risks that the technologies might pose and finally the governance strategies that might be applied to minimize the risks. In his introduction the editor made it obvious that the frame of analysis was dual use and bioterrorism with subsections on defining dual use, the dual-use landscape (past and present), the rise of synthetic genomics, technical hurdles to bioterrorism, and so on.

The chapter on TMS was written by Jonathan Moreno and shows that while the mechanism of action is not understood (Moreno 2012a):

> . . .Over the past twenty years, repetitive TMS has evolved from an experimental diagnostic technique into a mature technology that has been approved for treatment of major depressive disorder and has other promising clinical applications.

However, the production of the equipment and diffusion of the technology remains relatively limited:

> . . .The number of vendors of TMS equipment today is limited, although interest in the therapeutic use of the technology is growing amongst advanced industrial countries.... Once the safety and efficacy of TMS have been demonstrated, it is likely to spread to additional countries.

So should there be potential for misuse of TMS, it is not yet impossible to put in place sensible control mechanisms such as those being developed in regard to aspects of synthetic biology (Garfinkel et al. 2007).

TMS is not in the category of a technology that could be misused to create a weapon of mass destruction (WMD), but the author of the essay, who has given considerable thought to the misuse of neurotechnologies (Moreno 2012b), lists a series of possible concerns. In his view:

> Repetitive TMS is a clear case of a dual-use technology.... Given the limited expertise needed to employ the technique. . . states or terrorist organisations could potentially misuse it for harmful purposes....

He lists, for example, “erasing” the memory of someone to make him unable to disclose information under interrogation or to “enhance” the ability of a terrorist to carry out an attack.

Moreno also cites the interest of the US military in TMS and its possible deployment in the field within one or two decades to enhance “top-down visuospatial attention” in combination with fMRI and this perhaps leading to an

enhancement arms race in which soldiers have to accept increasing amounts of cognitive modification. The reason for the military interest in technologies like TMS was set out in an article by a team with a member of the US Air Force Research Laboratory as the lead author (McKinley et al. 2012):

> . . .These techniques are perhaps best suited for career fields where certain cognitive skills such as vigilance and threat detection are essential in preserving human life. Because such jobs are plentiful in the military, it is no surprise that the US Air Force has recently begun investing in noninvasive brain stimulation for its efficacy in benefiting human cognitive performance....

Perhaps of more concern, Moreno cites recent work (Young et al. 2010) which suggests that TMS might be misapplied to manipulate moral judgements or beliefs about right and wrong, it seems, by elevating consideration of the outcome of another's actions above their intent, through disruption of the right temporoparietal junction.

What is of particular interest is the discussion of the options for governance. It should be noted here that the author of a study of the promises and perils of noninvasive brain stimulation (Heinrichs 2012) to my mind appears to totally misunderstand the problem of dual use when he concludes that "most issues in medical and research ethics such as . . .potential for misuse can be handled with manageable effort" as that is precisely what cannot be achieved in regard to dual use and why there has been so much concern. The problem is that benignly intended work, carried out quite properly according to accepted required standards, might later be misused by others. In his chapter Moreno suggests two different options. First, since there are still a limited number of manufacturers, it should be possible to track international sales (even if it is difficult to be sure of how the equipment is used after the sale). Second soft-law and informal approaches such as awareness-raising of possible misuse among users and the development of education and codes of conduct might be developed. The final chapter of the book (Bansak and Tucker 2012) sets out the assessment of the risks of misuse and of the governance possibilities for each technology in tabular form. Then in a final table, the risk of misuse of each technology is compared with its potential governance. It is worth quoting the conclusion in full in regard to TMS:

> The technology in the lower right-hand corner of the matrix, transcranial magnetic stimulation (TMS), poses a low risk of misuse because it can be applied to only one individual at a time rather than to a large group or population. For this reason, the potential misuse of TMS to support coercive interrogation or to erase memories is more of a human rights concern than a potential threat to national security. . . .

And the text continues to assert that:

> . . . At the same time, TMS has a high governability score because its clinical use is heavily regulated on safety and ethical grounds. That TMS consists primarily of hardware also makes it more susceptible to governance. Because the risk of misuse of TMS is low, the technology does not warrant the development of governance strategies.

Dealing first with the question of the numbers of people who might be affected, the article quoted previously (with the member of the US Air Force Research

Laboratory as lead author) makes clear the current demands for data analysis in Iraq and Afghanistan (McKinley et al. 2012):

> . . .Each combat air patrol (CAP) currently consists of 4RPA [Remotely Piloted Aircraft], 43 personnel for mission control, 59 for launch and recovery and 66 for processing, exploitation and dissemination. Not surprisingly, the strain on manpower is one of the major challenges facing the Air Force in coming years....

So to accept the argument for ignoring governance of TMS, we have first to set aside the prospect of thousands of soldiers (including conscripts) spending their working days subject to a technology of unknown long-term health consequences. The main point, however, is that on this reading the government should not spend any effort – not even awareness-raising and education on dual use and biosecurity – in regard to TMS. The dual use/bioterrorism puts the focus elsewhere.

On the other hand, taking the view that bioterrorism is not going to be a major problem for some time and that the real problem we face is preventing the wholesale militarization of the life sciences suggests a quite different answer. Particularly, given the difficulty of controlling technologies once they have been incorporated into military equipment and operations, should we not, instead of ignoring TMS, take the opportunity provided by the possibility of its governance to go all out to get it under control now? At least attempting to reach that objective would provide the neuroscience, neuroethics, and policy-making communities experience and models that could help in the future as the revolution in the life sciences and more difficult problems related to militarization and potential hostile misuse develop.

BCIs

As the Nuffield Council's consultation paper explained, in a BCI (Nuffield Council on Bioethics 2012):

> Patterns of electrical activity in the brain that accompany an individual's thoughts and intentions give rise to characteristic brain signals which can be detected.... These electrical signals can be analysed and converted, with the help of a computer, into various commands and appropriate actions....

The paper goes on to note a number of BCI applications that are known to be of interest to the military such as augmentation of muscle strength for the individual soldier and to enable remote control of vehicles. What is of particular interest here is the view expressed that (Nuffield Council on Bioethics 2012):

> . . .Finally, 'telepresence' is where a soldier, whilst physically present elsewhere, has the ability to sense and interact in a removed and real world location, such as with a demolition robot or unmanned vehicle (drone) through a BCI connection.

So the council has decided to examine two technologies that are of increasing importance to the military: TMS, as we have seen, is a possible means of

enhancing data analysis from remote sources, and BCIs could be important in the future as part of a control system for the operation of drones. The association of these two noninvasive neurotechnologies with advances in information technology (IT) is crucial to grasp because developments in IT are critical for military forces at the present time as they seek to gain technological superiority in this field. Thus it can reasonably be argued that the council is carrying out a study of one of the current cutting edges in the militarization of neuroscience.

One recent US analysis considers the impact of IT on military superiority in the future. IT is viewed in this analysis as an exponentially growing technology as it is one in which "performance per dollar multiplies over time." Such exponential growth in military-related technologies can produce opportunities (Kopp 2012):

> . . .to devise entirely new solutions to longstanding, or entirely new problems. . .[these] can frequently produce highly disruptive effect, as the new solution will often exploit systemic weaknesses in the opponent's capabilities that cannot be easily overcome by established means.

Given that IT is available commercially around the world, the paper suggests that all players are on a level playing field, and in such circumstances "the player who can best exploit talent to an advantage - all else being equal - will inevitably win."

It is in that general context and the increasing use of remotely piloted aircraft, drones or unmanned aircraft systems (UASs) that the potential use of TMS and BCIs in such equipment has to be considered. This is not a theoretical problem, as concerns about the use of drones for assassination purposes among international lawyers amply illustrate (Bowcott 2012).

Any doubt as to the potential involvement of BCIs in the long-distance control of UASs is easily dispelled by a minimal review of the literature that goes beyond simple extension of human capabilities like robotic arms (Brunner et al. 2011). For example, a paper published in 2011, reported utilization of a noninvasive BCI system employing EEG recordings of sensorimotor rhythms (SMRs) to demonstrate human capabilities to exert three-dimensional control of a virtual helicopter. The paper suggested that (Doud et al. 2011):

> . . .three-dimensional movement of a virtual helicopter. . .is fast, accurate, and continuous. In this system, the virtual helicopter's forward-backward translation and elevation controls were activated through the modulation of the sensorimotor rhythms that were converted to forces applied to the virtual helicopter at every simulation time step, and the helicopter's angle of left or right rotation was linearly mapped, with high resolution, from sensorimotor rhythms associated with other motor imagination. . . .

It is fanciful to imagine that such work is not of interest to the military even if there is no indication of military funding for this particular publication.

The UK Ministry of Defence (MOD) has certainly taken the moral, legal, and ethical issues involved in the operation of UASs seriously, devoting a separate chapter to discuss them in its Joint Doctrine Note 2/11 on *The UK Approach to*

Unmanned Aircraft Systems (Ministry of Defence 2011). In this publication careful differentiation is made between an unmanned aircraft and an unmanned aircraft system. The latter is defined as:

> . . .a system, whose components include the unmanned aircraft and all equipment, network and personnel necessary to control the unmanned aircraft.

All operations by UASs are governed by the Law of Armed Conflict (LOAC):

> . . .Firstly, weapons law guides whether a weapon and its generic uses are lawful; secondly, targeting law determines whether the use of a particular weapon is lawful on a specific mission or in specific circumstances....

This raises questions such as whether a remote pilot has adequate knowledge to make reasoned judgements about proportionality and discrimination. The law of armed conflict (International Humanitarian Law, IHL) is based on the concept of legal responsibility. As the MOD paper notes, "[L]egal responsibility for any military activity remains with the last person to issue the command authorising a specific activity."

Also of interest here is also the legal status of the remote operator. In a section on "The Remote Warrior," the paper asks a series of difficult questions:

> . . .With kinetic operations being controlled from several thousand miles away, such as those in Afghanistan currently being conducted from the continental US, LOAC issues are further complicated. The concept of *fighting from barracks* as it has been termed raises a number of interesting areas for debate....

These questions, as the MOD paper sets them out, include:

> . . .Is the *Reaper* [UAS] operator walking the streets of his home town after a shift a legitimate target as a combatant? Would an attack by a Taliban sympathiser be an act of war under international law. . .? Does a person who has the right to kill as a combatant while in a control cabin cease to be a combatant that evening on his way home?....

Going beyond the legal issues, the paper raises a number of what it sees as moral and ethical issues such as whether the capability to wage war from a distance with no risk to our soldiers' lives risks unnecessary escalation of conflicts and brings the legitimacy of our actions into question.

Autonomous Weapons

What is most striking about the MOD paper, however, is the constant concern about the likely coming of autonomous systems and the implications, legal and ethical, of that future. For example, the paper notes the increasing complexity and pace of modern warfare:

> . . .There is also an increasing body of discussion that suggests that the increasing speed, confusion and information overload of modern war may make human response inadequate and that the environment will be '*too complex for a human to direct*' and this has already been exemplified by the adoption. . .of autonomous weapon systems. . . .

Such considerations raise more difficult questions about responsibility:

> . . . Is a programmer guilty of a war crime if a system error leads to an illegal act? Where is the intent required for an accident to become a crime?

And the paper considers that there is an urgent need for policy development:

> . . . The pace of technological development is accelerating and the UK must establish quickly a clear policy on what will constitute acceptable machine behaviour in the future; there is already a significant body of scientific opinion that believes in banning autonomous weapons outright, countered by an acceptance in other areas that autonomy is inevitable....

The net result of the analysis in this chapter of the MOD paper is bleak:

> . . .There is a danger that time is running out - is debate and development of policy even still possible, or is the technological genie already out of the bottle, embarking us all on an incremental and involuntary journey towards a *Terminator*-like reality?

My own answer to that question is probably yes, but not necessarily, as the implementation of a new technology is not preordained but contingent on social processes (Price 1997) and there are certainly efforts under way, for example, by the International Committee of the Red Cross to avoid such an outcome. The ICRC is certainly clear about the importance of dealing with the question of autonomous weapons (ICRC 2011):

> An autonomous weapon system is one that can learn or adapt its functioning in response to changing circumstances in the environment in which it is deployed. A truly autonomous system would have artificial intelligence that would have to be capable of implementing IHL. Such systems have not yet been weaponized although there is considerable interest within expert literature and considerable funding of relevant research. The deployment of such systems would reflect a paradigm shift and a major qualitative change in the conduct of hostilities. It also raises a range of fundamental legal, ethical and societal issues which need to be considered *before* such systems are developed or deployed.

The difficulties of dealing with autonomous weapons, however, were recently exemplified by the failure even to get these weapons into the draft of the Arms Trade Treaty (Bolton 2012).

Moral Machines?

Although the work of neuroscientists could be seen as helping to take us down the road to autonomous weapons, it could be argued that once such systems are in place, there is little point in asking more questions of neuroscientists. However, that is to ignore the fact that their technologies are also part of the investigatory apparatus of neuroscience that is being used to research moral decision-making. Moreover, neuroscience may also be involved in further advances in which new information technologies materials and methods are derived from our growing understanding of the operations of the nervous system (see, e.g., the US DARPA projects on NeuroVision 2 and Systems of Neuromorphic Adaptive Plastic Scalable Electronics – SyNAPSE – as described on the Defence Sciences

Office section of the DARPA website www.darpa.mil). Therefore, it seems to me that neuroscientists will have a continuing responsibility to help guard their work from misuse.

The problem caused by the progress of modern information technology is that in warfare there is a deluge of new data from sources such as drones. TMS may be useful in helping soldiers to handle such data, and BCIs may be useful in reducing the time needed to respond to the data input, but eventually there will be limits to such solutions so that it becomes inevitable on this logic that autonomous weapon systems will have to be developed and deployed. These can be made to deal with larger amounts of data and never get tired, but as the MOD paper points out (Ministry of Defence 2011):

> . . .To a robotic system, a school bus and a tank are the same - merely algorithms in a programme - and the engagement of a target is a singular action; the robot has no sense of ends, ways and means, no need to know **why** it is engaging a target. . . .

For some the solution to that problem is to design moral machines that can apply the Law of Armed Conflict better and more consistently than human beings.

Ronald Arkin, a US engineer who takes his responsibilities for the social impacts of his work very seriously (Bookman 2011), has argued, for example, that (Arkin et al. 2012):

> Weaponised military robots are now a reality. While in general a human remains in the loop for decision making regarding the deployment of lethal force, the trend is clear that targeting and engagement decisions are being moved forward onto these machines as the science of autonomy progresses. . ..

He therefore has put forward:

> . . .the research hypothesis that autonomous systems could ultimately operate more humanely than human warfighters are able to. As part of the research to test this thesis funded by the Army Research Office, an ethical architecture for an autonomous system was developed with the intent of enforcing the principles derived from LOW [Laws of War], thus having the goal of enhancing noncombatant safety and survivability. . ..

Others have argued that ethical judgements are complex and unlikely to be easily programmed into a machine (Prichard 2012) – even if the data required would be available to the machine in the “fog” of war.

Whether moral machines can be built is an empirical issue that will be decided later, but what is not in doubt is that the work of neuroscientists will be utilized in the process of deciding (Arkin et al. 2012):

> . . .researchers should utilize biologically relevant models of ethical behaviour as the basis of research: drawing heavily on ethology, neuroscience, cognitive psychology, and sociology as appropriate as a basis. . ..

Moreover, as progress is made in understanding of how we make moral decisions, it is surely likely that modification of ethical behavior in civil society through means such as TMS will come to be increasingly discussed (Heinzelmann et al. 2012).

Conclusion

People in the military/security field have remarked to me that we civilians have difficulty looking through "the dark side of the telescope." We do not naturally think about people intending to do harm, or as Andy Stirling put it in his essay on the governance of neuroscience for the Royal Society Brain Waves Module 1 (Stirling 2011):

> . . .Although readily foreseeable in the same terms as benign uses, malign applications are typically underestimated in regulatory assessment. . .. Yet easily anticipated effects may be of a magnitude that seriously jeopardises overall benefits. This is exemplified by the paradox that military aims are at the same time so prominent and so under-scrutinised in global research. Roughly one third of worldwide human effort in research and innovation is devoted – directly or indirectly – to refining ways to perpetrate premeditated organised violence. . ..

This section of the essay is subtitled "See no evil."

I therefore took it that my task in this paper was to try to give some idea of what the advances in neuroscience might look like from the biosecurity "dark" side in the hope that this could convey some of the issues that would be considered important to the security community and those, like myself, who hope to develop better means to restrict violence.

In an important multiauthor paper published in *The Columbia Science and Technology Law Review* (Marchant et al. 2012), the rise of autonomous military robotics is outlined and the ethical and policy issues are described. Then currently available governance mechanisms are reviewed, and it is concluded that "contemporary governance architecture regarding the innovation and use of military robots would appear wholly inadequate to the task." Finally, the range of possible future governance mechanisms, from legally binding "hard-law" to "soft-law" approaches, such as codes of conduct, are discussed. The authors do not suggest which approach should be used but call "for a national and international dialogue on appropriate governance of such systems *before* they are deployed." I agree, but note that at present most neuroscientists would not be able to contribute to the dialogue and would probably not even know that it was taking place.

Consequently, I would urge the support of the recommendation of the Royal Society Brain Waves Module 3 on *Neuroscience, conflict and security* in its first recommendation that (Royal Society 2012):

> There needs to be a fresh effort by the appropriate professional bodies to inculcate the awareness of the dual-use challenge (i.e., knowledge and technologies used for beneficial purposes can also be misused for harmful purposes) among neuroscientists at an early stage of their training.

Moreover, the UK has made clear that it supports this approach strongly (United Kingdom 2012):

> . . .The UK shares the view that it is important to look at how the issue of dual-use can be assimilated with broader professional training for scientists in the university curricula in a holistic and sustainable manner both at home and abroad. . ..

As Michael Tennison and Jonathan Moreno concluded in their recent review of the state of the art in the field of neuroscience, ethics, and national security if neuroscientists were aware and educated (Tennison and Moreno 2012):

> . . .Just as many nuclear scientists opposed the development of atomic weapons, contributing to the test ban treaties of the 1960s and the drawdown of armed missiles in the 1980s. . .neuroscientists could consider and promulgate their perspectives on the military implications and ethical issues associated with their work.

As has been cogently argued, it would be best to base such education on the ideas of Responsible Conduct of Research that scientists already have begun to assimilate (Carlson and Frankel 2011) by adding consideration of "external" aspects such as dual use to the "internal" aspects such as research misconduct. Nevertheless, it surely will be necessary to supplement that with at least a basic framework of ethics if scientists are going to contribute effectively to protecting their benignly intended work from hostile misuse.

International Legal Restraints on Chemical and Biological Weapons

115

Catherine Jefferson

Contents

Abstract

Therapeutic advances in neuropharmacology and drug delivery could be exploited for the development of incapacitating biochemical weapons. This chapter examines the international legal restraints on chemical and biological weapons, with a particular focus on arms control law, human rights law, and international humanitarian law. It also examines the legal implications of other potential neuroweapons, such as neural-interface weapons systems, with a particular focus on the challenges posed to notions of criminal responsibility.

Introduction

Advances in neuroscience and understandings of the brain promise great benefits to society, particularly in the treatment of neurological impairment and psychiatric

disease. However, as an unfortunate precedent attests, every major innovation in science and technology has been exploited for hostile purposes, and the life sciences have proven to be no exception (Meselson 2000; Kelle et al. 2012). While advances in neuropharmacology and drug delivery may offer improved therapeutic options, these same advances may also suggest ways in which human health can be impaired and could be exploited to do harm through the development of chemical and biological weapons (Royal Society 2012; ► Chap. 114, “Neuroscience Advances and Future Warfare” this section). This chapter examines the body of international law in place that prohibits these weapons, with a particular focus on arms control law, human rights law, and international humanitarian law. Finally, it examines some of the legal implications of other potential neuroweapons, with a particular emphasis on criminal responsibility.

Arms Control Law

Chemical and biological weapons (CBW) are weapons that are intended to do harm by affecting life processes, through either the toxicity of chemicals or the infectivity of pathogenic microorganisms. CBW are prohibited by two mutually reinforcing treaties that ban the use, development, and procurement of these weapons – the 1993 Chemical Weapons Convention (CWC) and the 1972 Biological Weapons Convention (BWC). As Table 115.1 illustrates, there is some overlap between the agents that are covered by these two treaties, and while there exist a number of distinguishing features between chemical weapons on the one hand and biological weapons on the other (such as toxicity versus contagiousness or incubation period), they are perhaps more appropriately conceptualized as a threat spectrum rather than distinct categories of weapons.

The norm against the use of poison and disease as a weapon can be traced throughout history and across various different cultures, but the first multilateral agreements to prohibit the use of poison or poisoned weapons in war were the Hague Conventions of 1899 and 1907, which also included provisions against the use of asphyxiating gas (Jefferson 2009). While the Hague Conventions were unsuccessful in averting the wide-scale use of gas in the First World War, the prohibition on CBW was reaffirmed with the signing of the Geneva Protocol of 1925, which remains in effect today and has provided the normative basis for the development of the CWC and BWC. Yet despite the legal regime that is in place to prohibit CBW, challenges remain. Of particular interest to this chapter is the perceived ambiguity within the provisions of the CWC, which, teamed with the perception that advances in neuroscience could offer feasible “incapacitating” biochemical weapons, risks undermining the regime against CBW.

Chemical Weapons Convention

The 1993 CWC provides a comprehensive ban on chemical weapons, including a ban on their development, production, and stockpiling, as well as use. However, the CWC contains a number of exceptions whereby the production and use of toxic chemicals is permitted, being:

(a) Industrial, agricultural, research, medical, pharmaceutical or other peaceful purposes;
(b) Protective purposes, namely those purposes directly related to protection against toxic chemicals and to protection against chemical weapons;
(c) Military purposes not connected with the use of chemical weapons and not dependent on the use of the toxic properties of chemicals as a method of warfare;
(d) *Law enforcement including domestic riot control purposes*. (CWC Article 2.9)

It is through this law enforcement exemption that ambiguity has arisen. First, the CWC does not state explicitly what is meant by "law enforcement" or what law States may enforce, where or under what circumstances. As such, Article 2.9(d) could be interpreted to permit the use of toxic chemicals to enforce domestic law extra-jurisdictionally or to enforce international law (Meselson and Robinson 1994). However, the CWC is clear that riot control agents are prohibited as a method of war (CWC Article 1.5).

Secondly, and more presciently for this discussion, is the ambiguity in the interpretation of the range of toxic chemicals permissible for law enforcement purposes. While, as noted above, riot control agents are prohibited as a method of war, Article 2.9(d) protects the use of chemicals such as tear gas for domestic riot control purposes in the context of law enforcement. Riot control agents are defined

by the CWC as "any chemical not listed in a Schedule, which can produce rapidly in humans sensory irritation or disabling effects which disappear within a short time following termination of exposure." However, Article 2.9(d) stipulates that the production and use of toxic chemicals may be used for law enforcement *including* domestic riot control purposes, yet the Convention provides no definition of what these other chemicals may be. This ambiguity could thus be interpreted to suggest that the range of toxic chemicals permitted for law enforcement goes beyond riot control agents to also encompass so-called incapacitating chemical agents, i.e., centrally acting agents intended to cause rapid but more prolonged incapacitation through "loss of consciousness, sedation, hallucination, incoherence, paralysis, disorientation or other such effects" (Royal Society 2012).

The CWC distinguishes between three classes of toxic chemicals and their precursors. Schedule 1 chemicals have few or no uses outside of chemical weapons; Schedule 2 chemicals have legitimate small-scale applications; and Schedule 3 chemicals have large-scale uses apart from chemical weapons. The CWC is explicit that States Parties are prohibited from producing, acquiring, retaining, or using Schedule 1 chemicals for law enforcement purposes (CWC Verification Annex VI.2). Schedule 2 and 3 chemicals are permitted but are subject to Article 2.1(a) of the CWC, which restricts the development, possession, and use of toxic chemicals according to "types and quantities" consistent with permitted purposes. As Meselson and Robinson ask:

> Is the Convention really to be read as allowing any non-Schedule-1 toxic chemical or precursor to be developed, produced, weaponized, stockpiled or traded, so long as it is said to be for 'law enforcement purposes'?. (Meselson and Robinson 1994)

Experts in the field of CBW control and nonproliferation argue that such an interpretation is untenable and that only riot control agents should be considered permissible for law enforcement purposes, with the special exception of toxic chemicals used as a means of capital punishment (i.e., lethal injection). The special case of chemical executions in the USA, it is argued, should not be exploited for wider interpretations of law enforcement that go beyond riot control agents (Kelle 2012a).

On the other end of the spectrum, there are strong indications of State interest in the development of incapacitating chemical agents, ostensibly for law enforcement purposes (Crowley 2009). One of the more widely documented examples is the use by the Russian Federation of an incapacitating chemical agent reportedly a derivative of fentanyl, believed to be a mixture of carfentanil and remifentanil (Royal Society 2012). In October 2002, a group of armed Chechen separatists stormed the Dubrovka theater in Moscow and took approximately 830 people hostage, demanding withdrawal of Russian troops from Chechnya. On the third day of the hostage crisis, Russian special forces disseminated the incapacitating chemical agent through the theater's ventilation system, incapacitating both the hostages and the hostage-takers. The theater was then stormed by troops who killed the hostage-takers and freed the hostages. While the siege was brought to an end, 129 of the hostages died as a result of complications following the use of the incapacitating chemical agent and many others suffered long-term effects (Wax et al. 2003).

The perception of the need for improved operational capabilities, for example, in scenarios such as counterterrorism and counterinsurgency, teamed with insights gained from advances in neuroscience, is continuing to fuel State interest in incapacitating chemical agents. There are a wide range of neuropharmacological agents that could be considered as candidate agents for incapacitation, including opioids such as fentanyl and its derivatives, benzodiazepines, alpha-2-adrenoceptor agonists, and neuroleptic anesthetics. Advances in the knowledge of bioregulatory peptides could also offer novel means of incapacitation. While biochemical compounds that control vital homeostatic systems, such as temperature, sleep, and blood pressure, occur naturally at low concentrations, they can be toxic at higher concentrations. For example, research conducted on the effect of the aerosolized neuropeptide substance P found it to be fatally toxic when absorbed into the lungs of test animals (Koch et al. 1999). Developments in understandings of bioregulators and receptor systems could therefore be exploited to induce unconsciousness. Recent research into orexin receptor antagonists for the treatment of insomnia, for example, could suggest possible applications for the development of an incapacitating chemical agent (Royal Society 2012).

Despite these potential advances, numerous studies have highlighted the challenges of creating a genuinely "nonlethal" incapacitating chemical agent. One of the biggest challenges is the dose–response problem, that is, for an agent to be effective in its goal of reliable incapacitation, the dose required would generally be expected to cause a level of fatality. This was clearly demonstrated in the use of an incapacitating chemical agent by the Russian Federation during the theater siege. As one commentator has noted:

> The fentanyl, however, killed approximately 130 hostages – a fatality rate of 16 %, more than twice the fatality rate of "lethal" chemical weapons used on World War I battlefields. (Fidler 2005)

Determining an acceptable threshold of fatality is problematic, and even if an acceptable safety margin could be established under clinical control, it is doubtful that this could be replicated in an operational scenario. The dissemination of the agent in tactical situations would require pulmonary rather than intravenous delivery, which raises challenges for ensuring uniform dose delivery. Even if uniform delivery could be established, the target, being thus incapacitated, will remain in the contaminated area, possibly leading to prolonged exposure unless the person or the agent is removed (BMA 2007). As a recent UK Royal Society report summarizes:

> In addition to the technical challenge of combining an agent of sufficient safety margin with a dose controlled delivery system, uncontrollable variables such as variability of target population, secondary injury (eg, airway obstruction) and the need for medical aftercare make the feasibility of a totally safe incapacitating chemical agent unlikely. (Royal Society 2012)

Even if these technical challenges could be surmounted, when interpreting Article 2.9(d) of the CWC, States should take in account the object and purpose of the Convention: "…for the sake of all mankind, to exclude completely the

possibility of the use of chemical weapons...” (CWC Preamble). As various commentators have noted, the proliferation of incapacitating chemical weapons could weaken restraints on the use of lethal forms of chemical weapons, thereby threatening to undermine the regime against CBW and the norm against the use of poison and disease as a weapon:

> The continued development and use of toxic chemicals as weapons for law enforcement is likely to present broad and unpredictable risks for security, including inevitable proliferation... Depending on the extent of proliferation there could be the risk of an “arms race” of new chemical weapons and defensive countermeasures, which could be accentuated by any military acquisition of these weapons. (ICRC 2012)

At the time of writing, the Third Review Conference of the CWC is approaching (April 2013), and it is hoped that action will be taken toward a common understanding of the law enforcement provision and the status of incapacitating chemical agents.

Biological Weapons Convention

The 1972 BWC provides a comprehensive ban on biological and toxin methods of warfare. The BWC prohibits “microbial or other biological agents, or toxins whatever their origin or method of production, that have no justification for prophylactic, protective or other peaceful purposes” (BWC Article 1.1). The BWC is therefore comprehensive in its scope, and since certain candidate incapacitating agents, such as bioregulators and peptides, would be considered biological agents or toxins (see Table 115.1), these would also be prohibited by the BWC.

One potential area of ambiguity within the BWC is the definition of “peaceful purposes” and “hostile purposes.” It is unclear, for example, how the use of incapacitating biochemical agents for counterterrorism, counterinsurgency, or operations other than war would be regulated by the BWC. However, a number of States Parties to the BWC have highlighted the dangers to the BWC of the misuse of bioregulators and peptides in the development of incapacitating agents.

Human Rights Law

Given the ambiguities within the CWC regarding the potential development of incapacitating chemical agents, some commentators such as the ICRC have looked to other bodies of law to reinforce limitations on the use of toxic chemicals in the context of law enforcement.

International human rights law prohibits torture and cruel, inhuman, or degrading treatment or punishment and protects the right to life by placing constraints on the use of force. While it is not totally prohibited for an authorized agent of the State to have recourse to lethal force, the use of any weapon in a law enforcement context must be based on the criteria of lawfulness, necessity, and

proportionality (Casey-Maslen 2011). Given the risks of lethality, the use of incapacitating chemical agents for law enforcement purposes could therefore be called into question under international human rights law.

The death of 129 hostages following the use of an incapacitating chemical agent by the Russian special forces in an attempt to resolve the 2002 Moscow theater siege, and the failure of the authorities to disclose the chemical used, has been subject to scrutiny under international human rights law. In July 2003, eighty former hostages filed a complaint to the European Court of Human Rights, claiming their right to life had been violated by the actions of the Russian authorities.

In 2011 the European Court of Human Rights ruled that the Russian government had violated the right to life of the hostages through inadequate planning and implementation of the rescue operation but not on the basis of the chemical agent used. As Kelle has argued, this raises a number of problems:

> Apart from the fact that the use of a toxic chemical by Russian Special Forces clearly did not leave any chance of survival to 125 of the hostages, such an effects-based understanding of indiscriminate use of force seems strangely at odds with the established principles of the law of armed conflict. (Kelle 2012b)

A further problem relates to the Court's distinction between lethal and nonlethal use of force based on intention, i.e., it is assumed that the gas was a nonlethal incapacitating weapon since it "was probably not intended to kill the terrorists or hostages" (ECHR 2011). On the other hand, the Court found that the gas "remained a primary cause of death of a large number of victims" (ECHR 2011).

Some commentators have argued that this ruling can be interpreted as legitimizing the use of incapacitating chemical agents for law enforcement (Kelle 2012b). On the other hand, it reinforces the difficulties of actual implementation, as the ICRC note:

> . . .it is evident that the dose of a chemical delivered cannot be controlled in such a tactical situation and that it is extremely difficult, if not impossible, in such situations to provide the immediate medical care that might be characterised as adequate to protect life. (ICRC 2012)

International Drugs Control Law

International drugs control treaties are another source of international law that limits States' use of toxic chemicals. The 1961 Single Convention on Narcotic Drugs, as amended by the 1972 Protocol, the 1971 Convention on Psychotropic Substances, and the 1988 UN Convention Against the Illicit Traffic in Narcotic Drugs and Psychotropic Substances place strict limits on certain controlled toxic chemicals. These treaties limit the possession, use, trade, and production of narcotic drugs exclusively to medical and scientific purposes. The legitimacy of States Parties developing and using narcotic drugs for activities such as law enforcement is therefore called into question (ICRC 2012).

International Humanitarian Law

In addition to restraints on the potential law enforcement applications of neuroscience, potential military applications of neuroscience are also constrained by international humanitarian law (IHL), sometimes referred to as the laws of war or law of armed conflict, which seeks to limit the effects of armed conflict. IHL is primarily comprised of the Geneva Conventions of 1949 and the Additional Protocols of 1977 relating to the protection of victims of armed conflicts as well as other agreements prohibiting or regulating the use of specific weapons, such as the CWC and BWC.

The Geneva Conventions of 1949 and the Additional Protocols of 1977 (Protocols I and II) provide an extensive regime for the protection of victims of armed conflict. Within this regime, a number of provisions are particularly relevant in considering the use of incapacitating chemical agents in the context of armed conflict. For example, Article 41 of Additional Protocol 1 and Common Article 3 of the Geneva Conventions require the humane treatment of all persons in enemy hands, including civilians and members of the armed forces placed *hors de combat* (i.e., incapable of hostile action) by sickness, wounds, detention, or any other cause. As Article 41 of Additional Protocol 1 stipulates:

> 1. A person who is recognized or who, in the circumstances, should be recognized to be hors de combat shall not be made the object of attack.
> 2. A person is hors de combat if:
>   (a) he is in the power of an adverse Party;
>   (b) he clearly expresses an intention to surrender; or
>   (c) *he has been rendered unconscious or is otherwise incapacitated by wounds or sickness, and therefore is incapable of defending himself*;
>
> Provided that in any of these cases he abstains from any hostile act and does not attempt to escape. (Protocol 1, emphasis added)

The use of incapacitating chemical agents that render members of the armed forces *hors de combat* would therefore mean that affected persons must not be attacked by any other method from that time on. This presents particular concerns given that military personnel may not be able to recognize the signs of incapacitation. As an ICRC study asks:

> Due to the lack of physical evidence of injury, would an incapacitated person be more easily subjected to continued attack than persons rendered *hors de combat* by conventional weapons? (ICRC 2010)

The use of incapacitating chemical agents in armed conflict is also constrained by the principle of distinction:

> Rule 11: Indiscriminate attacks are prohibited.
> Rule 12: Indiscriminate attacks are those:
> (a) Which are not directed at a specific military objective;
> (b) Which employ a method or means of combat which cannot be directed at a specific military objective; or
> (c) Which employ a method or means of combat the effects of which cannot be limited as required by international humanitarian law;
>
> And consequently, in each such case, *are of a nature to strike military objectives and civilians or civilian objects without distinction*. (ICRC 2005, emphasis added)

Thus belligerents within a conflict must at all times distinguish between civilians and combatants, and attacks may only be directed against combatants. The use of incapacitating chemical agents in mixed combatant/civilian scenarios would therefore breech this principle (Herby 2007).

Other Neuroweapons?

The weaponization of neuroscience is not limited to the potential development of new chemical and biological weapons. One area of neuroscience that is attracting considerable attention is the potential for militaries to exploit neurotechnologies such as brain-machine interfaces that enable the direct neurological control of weapons systems. However, while neurologically controlled weapons are not necessarily prohibited by international humanitarian law per se, they do raise significant questions over notions of criminal responsibility.

Advances in brain-machine interfaces are enabling brain signals to be connected to specific hardware or software systems. It is conceivable that brain-machine interfaces could be utilized to enable direct neurological control of remotely operated robots, unmanned vehicles, or weapons systems. While legal responsibility for a military activity remains with the last person to issue the command, concerns have been expressed that advances in neuroscience could enable the development of weapons systems that blur the distinction between thought and action (White 2008). For example, electroencephalogram (EEG) studies have revealed that image processing can occur much more rapidly than the subject is consciously aware of, which could have implications for target detection (Royal Society 2012). A neurally interfaced weapons system that responds to neural markers could therefore provide advantages in terms of speed and accuracy of target detection but would remove the element of conscious human deliberation.

State practice has established that a serious violation of international humanitarian law in both international and non-international armed conflicts constitutes a war crime (ICRC 2005). War criminals may be brought before national courts, international criminal tribunals, or the permanent International Criminal Court, which is governed by the Rome Statute. However, if a war crime is committed by a semiautonomous weapons system, then determining criminal responsibility becomes more problematic. For example, the war crime of wilful killing could be committed if a neurally interfaced weapons system impacts on the ability to distinguish between legitimate combatants and civilians or people who have surrendered and thereby gained protection under international humanitarian law. Liability for such a war crime is seemingly unclear. As White has argued:

> If neural-interfaced weapons were designed to fire at the time of recognition rather than after the disambiguation process, a process that would likely need to occur for the pilot to differentiate between combatants and protected persons, the pilot firing them presumably would lack criminal accountability for the act implicit in wilful killing. *Because of the way brain-interfaced weapons may interrupt the biology of consciousness, reasonable doubt*

> *may exist as to whether an actor performed a conscious act in the event of a contested incident*. (White 2008, emphasis added)

This ambiguity has led to calls for an expanded doctrine of command responsibility in which designers and engineers of weapons systems could also be held responsible for aiding and abetting a war crime (White 2008). However, typically the responsibilities of designers are discharged once the system is certified by the relevant national authority (Gillespie and West 2010). This assumes that a system's basic principles of operation have been shown to be lawful as part of its release into service and that the individual giving orders will ensure its continued lawful use (MOD 2011). Legal responsibility will thus remain with the last individual to issue the command. However, given the complexities of some of the conceivable applications of neurally interfaced weapons systems, it is questionable whether such systems will continue to behave in a predictable manner after the command has been issued.

Neurally interfaced weapons systems therefore pose a number of legal dilemmas. Some commentators have argued for an outright prohibition on semi- and fully autonomous weapons (such as, the International Committee for Robot Arms Control). However, such a prohibition could hinder the development of weapons systems that may prove to be more accurate than existing capabilities. A balanced approach to future policy must be maintained in which parameters for accountability and acceptable machine control is established.

Conclusion

Advances in neuroscience offer a range of significant benefits to society. However, many of these developments could also be exploited for hostile applications, such as in the development of incapacitating chemical weapons. This chapter has provided an overview of the legal restraints on these weapons in both military and law enforcement contexts, drawing on arms control law, human rights law, and international humanitarian law. It has also examined some of the legal implications of potential developments in neurally interfaced weapons systems.

Despite the existence of a comprehensive regime of restraints against the development and use of incapacitating chemical weapons, studies have revealed a general lack of awareness among neuroscientists of the CWC and BWC. It has been noted by a number of commentators – and is formally recognized by the implementing bodies of the two treaties – that awareness raising among scientists is crucial for the effective implementation of the CWC and BWC. Greater awareness of the potential malign applications of neuroscience research and the legal regime that such applications would be subject to should therefore be encouraged.

Biosecurity as a Normative Challenge 116

Tatyana Novossiolova

Contents

Abstract

The ongoing progress of biotechnology constitutes a major governance challenge, not least because the same advances that promise to enhance human welfare could potentially enable the development of novel biological weaponry systems. To address the multifaceted security concerns arising from the life sciences, a range of top-down policy initiatives and legally binding regulations have been introduced, but their overall impact on the practices of life scientists has remained limited. Given that laws in every sphere of activity are dependent upon the vitality of social and/or professional norms, the chapter aims to enquire into the normative foundation of the biosecurity regulations. It contends that there is a disjuncture between the conduct of life scientists and the rules pertaining to biosecurity stemming from the lack of corresponding norms in the professional culture of life science research. This disjuncture largely manifests itself in three forms, namely, ignorance of the existing biosecurity regulatory framework, arrogance motivated mainly but not

exclusively by the belief that science should enjoy unconstrained freedom, and acts of open defiance of the rules. The chapter concludes by examining the value of biosecurity education and awareness raising in addressing the security challenges posed by biotechnology and fostering a culture of research that is keenly aware of and responsive to the norm of biological nonproliferation.

Introduction

The advancement of biotechnology over the past few decades promises to bring tremendous benefits by responding to health, societal, and environmental ills. At the same time, however, this progress poses fundamental ethical, legal, and social challenges, not least because the very same advances that could enhance public welfare could potentially facilitate the development of novel biological weapons and/or be misused for bioterrorist purposes and thus pave the way for the wholesale militarization of the life sciences. In February 2012, the British Royal Society published Brain Waves Module 3: Neuroscience, Conflict and Security, a report outlining the potential military and law enforcement applications of novel discoveries in the field of neuroscience. According to the report, such applications broadly pursue two main objectives, namely, improving the efficiency of one's own forces (performance enhancement) and diminishing the performance of one's enemy (performance degradation) (The Royal Society 2012). It further suggested that there are at least several major developments, including neuropharmacology, functional neuroimaging, and neural interference systems that immediately raise important ethical and legal issues (The Royal Society 2012). Unfortunately, to date, engagement among neuroscientists with the ethical, social, and legal aspects of their work has been limited. Far from being an exception, this trend appears common among life scientists in general. A series of interactive seminars carried out in 16 different countries with a several thousands of life scientists in over 110 different departments revealed that there was little evidence that the participants:

1. Regarded bioterrorism or bioweapons as a substantial threat
2. Considered that developments in life sciences research contributed to biothreats
3. Were aware of the current debates and concerns about dual-use research
4. Were familiar with the Biological and Toxin Weapons Convention (BTWC) (Dando and Rappert 2005; Rappert 2007, 2009)

By contrast, following the 9/11 assaults, the 2001 "anthrax letters" attacks and most recently the controversy surrounding the production of mammalian-transmissible avian influenza (H5N1), attempts to address the security implications of novel biotechnology advances have been high on the political agenda. Besides the 1975 BTWC, which outlaws a whole class of weapons of mass destruction (WMD), a whole range of legally binding instruments, regulations, codes, and guidelines have been devised at international, national, and institutional level in order to improve the governance of dual-use science and technology and ensure that the life sciences are utilized only for "peaceful, protective, and prophylactic purposes." While those documents have formally expanded the scope of

responsibilities incumbent upon those engaged in the life sciences, their practical implementation has been slow and patchy. A major hurdle in the process has been a widely shared perception among life scientists that biosecurity regulations are largely burdensome and unnecessary, creating extra paperwork and threatening to stifle innovation.

The purpose of this chapter is to account for the existing disjuncture between the practices and attitudes of life scientists, on the one hand, and biosecurity regulations, on the other. It advances the argument that the disjuncture stems from the fact that the regulations are not underpinned by corresponding norms in the professional culture of life scientists, which in turn impacts on their integrity and effectiveness. Section "The Power of Norms" elucidates the interplay between laws and norms, demonstrating the ways in which they reinforce one another. Section "Biosecurity and Risk in Science Practice" then conceptualizes biosecurity and examines the scientists' perceptions of risks of vis-à-vis the biosecurity discourse. Section "Biosecurity Regulations: Role and Limitations" gives an overview of biosecurity regulations, their role, and limitations. Section "The Disjuncture Manifested" looks into some the practices of life scientists and how they diverge from the established regulatory framework. The chapter concludes that addressing the security challenges posed by biotechnology requires a culture of research keenly aware of and responsive to the norm of biological nonproliferation.

The Power of Norms

Vickers suggests that there are three types of constraints that shape human motivation and action: logistical constraints that define the limits to what one can do, taking into account possible risks and uncertainty; constraints imposed by the wishes and expectations of others, including those imposed by powers of authority that define what one must or must not do within a society, group, or an organization; and constraints created by one's own personality system that define what one ought to do in order to meet one's own aspirations and expectations of oneself (Vickers 1972). In other words, what one can and cannot do, must and must not do, and ought and ought not do are subject to constraints imposed by circumstances, by other people and oneself, respectively (Vickers 1972). Thus, physical capacity and social status constitute logistical constraints, laws and norms serve as regulatory constraints, and morals are among the personal constraints that guide individual's deeds. This section will focus exclusively on the second type of constraints which in the widest sense relate to social obligation.

Laws are fundamental ingredients for the functioning of any society, not least because they draw a clear distinction between what must and must not be done and, as such, constitute the formal rules of behavior that every individual must obey. By design, the primary role of laws is to provide a basis for social order, which is why the extent of their effectiveness is directly proportionate to the degree to which they are abided by. In order to ensure maximum compliance with the law and limit the instances of disobedience, states rely upon various

enforcement mechanisms, including the use of police force and imposition of penalties. Yet, the value of legal rules notwithstanding, it is naïve to assume that law is the only or indeed the most important source of order within a social grouping. This is so, for people do not generally refrain from certain activities, such as stealing or committing assault, solely on the grounds of fear from incurring sanctions afterwards but rather because it is in their interest to do so. In other words, by accepting certain constraints on their personal freedom, individuals signal their inclination to cooperate with other members of society and contribute to the common good, thus enjoying benefits which otherwise will be unattainable. Not only does free riding then become a costly option but it also loses its attractiveness, as "cheaters" are hardly tolerated and likely to be ostracized (Becker 1996). A powerful social stigma on certain actions will undoubtedly have direct implications for the establishment of social order. To be sure, the members of a society in which theft and murder are commonly viewed as unacceptable acts that merit denunciation are much more likely to enjoy a relative degree of safety than those living in a society utterly dependent on law enforcement for tackling such problems. The shared expectation that cooperative behavior is rewarded, whereas cheating is penalized, facilitates the emergence of informal and unspoken rules which shape social relations and regulate the conduct of affairs in both public and private sphere – norms.

Norms are concrete, specific, and tacit standards (Vickers 1973) that signify what a particular social group considers acceptable and what unacceptable modes of behavior. Unlike laws, they are not dependent on government for either promulgation or enforcement (Posner and Rasmusen 1999). Rather, norms arise from and crystallize in the emergence of gradual consensus (Posner and Rasmusen 1999) as to what the members of a given group perceive as "normal" and are sustained by a shared recognition of their importance. Norms carry significant regulatory weight, insofar as they reflect the ethos of the group, that is, the beliefs, values, and morals shared by its members, and instances of noncompliance may have severe consequences. Thus, conformity with established norms both plays a paramount role in the maintenance of social order and constitutes an indispensable precondition for the functioning of law. As Tamanaha (2001) has pointed out, the "state legal system would not even exist, were it not for an already stable and effective baseline provided by the unarticulated substrate, shared norms, instrumental behaviour and consent."

Norms are inevitably subject to cultural and historical contingencies and tend to vary across communities. Far from being static, they evolve and change in parallel with social processes and practices. For their part, laws by and large, follow the dynamics of social norms and adapt accordingly. Laws that guarantee women's rights have only emerged as a result of the persistent efforts of the emancipation movements over the past century which challenged the prevalent norms of male superiority. Similarly, the collapse of the apartheid regime in South Africa would hardly have occurred had not it been for the lack of popular support for the established order (Whitman 2009).

The reverse process, however, whereby the creation of legal rules precedes or seeks to foster the development of social norms, is not so common. The history of

the human rights regime is a case in point. Brought about by the struggle of individuals everywhere to delegitimize the relations of absolute power, the human rights regime has played a major role in the abolition of colonialism, total war, and slavery. At the same time, the fact that practices as gruesome as female genital mutilation (FGM) and honor killing still persist in certain cultures even after the provision of the 1948 Universal Declaration of Human Rights has been formally codified in international and regional treaties and national legislation is indicative of the complexities of altering social norms. The obstacles to effective norm entrepreneurship are further illustrated in the reluctance of democratic governments to impose legal rules which are inconsistent with the prevalent social norms. Hence, the decision of President Lyndon Johnson to sign the Civil Rights Act of 1964 is often cited as an example of political courage, not least because of the public outrage that followed the new law, especially in the southern states. Needless to say, the Act required a substantial degree of enforcement in order to have an effect on lessening racial discrimination and segregation.

As the discussion above indicates, laws and norms are mutually reinforcing. It is also clear that while legal rules largely evolve from established customary practices, fostering norms via formal codes and regulations is a slow and arduous endeavor which often needs to overcome considerable resistance and, as such, can hardly succeed only by dint of enforcement. In light of those revelations, the subsequent sections aim to inquire into the normative foundation of the biosecurity regulations designed to address the governance challenges arising from the enormous dual-use potential of modern biotechnology.

Biosecurity and Risk in Science Practice

According to Dando (2010), the specter of threats to human health can be divided into three broad categories: naturally occurring disease, disease resulting from the accidental release of pathogens, and deliberately caused disease. Each of those threats is addressed through a distinct approach utilizing public health, laboratory biosafety, or biosecurity measures, respectively. Based on this understanding, biosecurity is closely linked to the idea of the "web of preventive policies" centered on the prohibition of the malevolent misuse of the life sciences embodied in the Biological and Toxin Weapons Convention (BTWC) (Novossiolova and Whitby 2011). As such, it is the objective of a whole range of rules and measures, including export controls, biodefense, and national implementation of the BTWC, designed to prevent the hostile release of pathogens by either state or non-state actors.

In light of the enormous dual-use potential of modern biotechnology and the resultant security challenges that strike right at the heart of the biological weapons nonproliferation regime, over the past decade novel biosecurity regulations which substantially expand the scope of responsibilities incumbent on those engaged in the life sciences have been introduced. The 1975 Biological and Toxin Weapons Convention (BTWC) is considered the cornerstone of the biological nonproliferation regime. Article I of the Convention formally prohibits work on pathogens and

toxins that have no justification for "prophylactic, protective, or other peaceful purposes." Yet to the rapid advancement of biotechnology poses a considerable threat to the regime, not least because it allows for benignly intended life science research to be potentially exploited for hostile purposes, including the development of biological weapons and bioterrorism.

Following the events of 9/11 and the "anthrax letters" attacks several states, most notably the USA, have developed and implemented strict rules and policies, designed to prevent the hostile exploitation of benignly intended scientific research. Two high-level reviews – Biotechnology Research in an Age of Terrorism (The Fink Report) and *Globalization, Biosecurity, and the Future of the Life Sciences* (The Lemon-Relman Report) – sought to draw attention to the issues of dual use by defining several potentially dangerous classes of research that warranted institutional review and oversight prior to being performed, and highlighting the important role that practicing life scientists could play in improving the governance of biotechnology.

Yet to date, there has been limited engagement of the life science community with biosecurity issues. Indeed, it is no exaggeration to say that while dual-use research may be a significant matter for security specialists and politicians, it is hardly a source of moral dilemmas for practicing researchers, as both the Fink and the Lemon-Relman Committees have suggested (NRC 2004, 2006). On the contrary, biosecurity concerns arising from cutting-edge biotechnology remain broadly unacknowledged and sometimes tend to be even purposefully ignored by those on the front lines of research. The recent controversy generated by two studies describing the creation of mammalian-transmissible avian influenza (H5N1) is indicative of both the propensity of life scientists to overstate the benefits of scientific research at the expense of potential security risks and the prevalent lack of awareness of biosecurity issues among the life science community. Had the vocal advocates of research on contagious H5N1 virus read the BTWC, they would have known that work involving the aerosolization of pathogens has direct implications for Article III of the Convention which states that State Parties undertake:

> not to transfer to any recipient whatsoever, directly or indirectly, and not in any way to **assist**, encourage, or induce any State, group of States or international organisations to manufacture or otherwise acquire any of the agents, toxins, weapons, equipment or means of delivery specified in Article I of the Convention. [emphasis added]

Curiously, one of the lead researches on the team in the Netherlands, where the more dangerous study was performed, was part of the group that prepared the national Code of Conduct for Biosecurity, which has the BTWC as its first appendix.

Unlike the instances of scientific misconduct, such as falsification, fabrication, and plagiarism, which are usually met with condemnation within the research community, the violation of biosecurity regulations rarely causes outrage. An illustration of this trend is the case of Dr Thomas Butler and the massive support from scientists it attracted. Butler was charged with offenses under the US PATRIOT Act for mailing and transporting vials of plague on passenger aircraft

and by road without obtaining the necessary documents and was sentenced to two years in prison and thousands of dollars in fines, as a result (Enserink and Malakoff 2003). Nevertheless, the Federation of American Scientists launched a large-scale campaign urging researchers to sign a petition in Butler's defense and formally blamed the US government for scapegoating a prominent plague scientist (FAS 2006).

The reasons for the apparent disjuncture between the practices of life scientists and the biosecurity regulations are complex and, as such, can hardly be reduced to incapacity of researchers to apprehend potential hazards and arrive at moral judgment. To grasp the intricacy of the challenge posed by dual-use research, therefore, it is essential to move beyond ethical reasoning at individual level and consider the structural and cultural contingencies that shape the science enterprise and determine the perceptions of risk of those involved.

The issue of dual use is problematic on at least three levels. First, science research is inherently of dual-use character, since virtually any knowledge or piece of technology, however basic, can be applied for multiple purposes. Hence, the potential threat posed by dual-use research is not one of *nature* but of *kind*, for it is the scale of the peril and the gravity of the consequences that ring the security bell. At the next level is the question of intent. By and large, scientists seek to generate knowledge and products that will enhance human health and welfare. Given their genuine desire to serve the public, it is often beyond the perception of the average researcher that the results of their work can be of use for those who want to cause harm. At the third and final level, the challenge is informational one. The majority of scientists are hardly aware of the wider social and legal implications of their research, not least because they work in conditions (e.g., academia, industry) and for purposes (e.g., vaccine development) which place their perceptions of the risks of their activity primarily within the sphere of laboratory biosafety (e.g., the prevention of accidental release of microbes) but not further. By contrast, in their greatest part, the biosecurity regulations reflect the views and risk perceptions of lawmakers and defense and intelligence specialists, people traditionally preoccupied with guaranteeing national security and barely aware of the realities of life science research.

Biosecurity Regulations: Role and Limitations

At an international level the biosecurity regulatory architecture comprises three legally binding instruments: the UN Security Council Resolution 1540, which imposes obligations on all state to enact legislation to prevent the proliferation of weapons of mass destruction, including biological weapons, and their means of delivery (UNSC 2004); the International Health Regulations which seek to "prevent, protect against, control and provide a public health response to the international spread of disease in ways that are commensurate with and restricted to public health risks" (WHO 2005); and the BTWC. States are obliged to develop and enforce legal mechanisms accordingly and report their annual progress on the

national implementation of the documents provisions. At a national level some states have already developed comprehensive governance frameworks designed to address the challenges arising from dual-use life science research. In the USA, the US PATRIOT Act, the 2002 Public Health Security and Bioterrorism Preparedness and Response Act, and the 2008 Select Agents Regulations, for instance, complement one another in mitigating the risks of a possible bioterrorist attacks by regulating the access to, transport, and handling of potentially dangerous pathogens and toxins. Likewise, in Canada, the 2009 Human Pathogens and Toxins Act serves as the cornerstone of a "safety and security regime" established to prevent the malevolent misuse of pathogenic microbes. Other measures implemented for the purpose of obstructing the deliberate spread of disease include personnel reliability programs, background security checks, university vetting schemes (e.g., UK), and national biosecurity codes of conduct (the Netherlands). Most recently, the US government has introduced a new policy for oversight of dual-use research of concern, and it is expected that other countries will mirror this example (Editorial 2012a).

By design, the biosecurity regulations seek to ensure that benignly intended life science research is not misused for hostile purposes, including the development of biological weapons and bioterrorism. As such, the regulations serve a twofold function, insofar as they are intended both to promote scientific innovation and reinforce the norm of biological nonproliferation. Unlike biosafety rules that define acceptable laboratory practices and procedures, the biosecurity measures address the possible social and security implications of research "beyond the laboratory door." In other words, whereas the former provide guidelines as to how research should be conducted in practical terms, the latter tackle a broader scope of issues, including what kind of experiments should be done, who should have access to hazardous materials and agents, and how the research results should be disseminated. The utility of laboratory biosafety regulations notwithstanding, their role in the governance of dual-use research is limited, as several controversial experiments have demonstrated. It suffices to note that the creation of a highly virulent strain of Mousepox, the artificial synthesis of the polio virus, the recreation of the 1918 Spanish Influenza, and the production of both strains of contagious H5N1 virus have been conducted under appropriate laboratory conditions and in compliance with the established biosafety rules. Preserving the integrity of the biological weapons nonproliferation regime therefore requires that a wider span of responsibilities should be assigned to life scientists in order to guarantee that the results of their work are not misused to cause harm.

The Disjuncture Manifested

As already discussed, laws in every sphere of human activity are largely dependent on the vitality and plasticity of both social and professional norms. The case of the biosecurity regulations is particularly curious, not least because there is little evidence that a corresponding norm of biosecurity practice exists. In contrast to

laboratory biosafety rules that form an essential part of the training of life scientists and are now deeply embedded in the conduct of research, biosecurity regulations are seen as an unnecessary bureaucratic burden devised to impinge on the development of science. Among the criticisms leveled at the regulations by scientists is that the former are too narrow in scope and, as such, inevitably neglect important aspects of the culture of biotechnology research, including the practices of peer review and dissemination of results, both of which take place in a highly globalized environment. Those and other limitations of the existing regulatory mechanisms have been made explicit during the lengthy debate on the publication H5N1 studies, leading the editorial board of a prominent scientific journal to conclude that restricting the spread of sensitive dual-use research via censorship and data-sharing on a need-to-know basis is impracticable (Editorial 2012b).

But the implications of the H5N1 controversy are well more far reaching, not least because the intensive deliberations on the value of the experiments have exposed the negligible role that the biosecurity regulations play in the risk-benefit calculations of those engaged in the life sciences. This disjuncture generally manifests itself in three ways. Ignorance about the legal and social implications of dual-use research is by far one of the most common manifestations. As Working Paper No.20 submitted by Australia et al. to the Seventh Review Conference of the BTWC in December 2011 noted:

> Continued academic research on bioethics and awareness of biosecurity risks seem to confirm a generally limited level of awareness among life scientists in numerous institutions in numerous countries. Analysis of the reasons for this lack of awareness include, *inter alia*, the lack of university courses covering aspects related to the BWC and related (bio-) security issues, either because the curriculum developers do not consider the topic to be important or have difficulty fitting teaching material on biosecurity into what they claim is an already overcrowded curriculum, or because of a lack of expertise and access to relevant teaching material. (WP.20/BWC/2011)

Even though the paper emphasized that the pervasive lack of awareness of aspects related to biosecurity and the obligations of the Convention among life scientists has to be addressed more urgently, strategically, and comprehensively (WP.20/BWC/2011), little has been done so far to fill the education gap and sensitize scientists to the security challenges arising from dual-use technologies.

The disjuncture is further signaled by dint of arrogance. Given that the ultimate goal of science is the pursuit of truth which in turn assigns it a special status, some have argued that any attempt to curtail research is detrimental to human progress:

> We do know that the potential is there, but it is not through fear that we will stop H5N1 from becoming pandemic. The pursuit of knowledge is what has made humans resilient – a species capable of overcoming our worst fears. (Perez 2012)

As a result, ethical and social issues barely feature in the context of scientific debates and security risks tend to be downplayed as exaggerated and hypothetical. On rare occasions, arrogance may escalate into defiance of rules. For instance, it was quite telling that one of the lead scientists on the team in the Netherlands that created a contagious strain of the H5N1 virus publicly declared his readiness to

disregard the export control ban imposed on his study by the Dutch government and submit his manuscript for publication without obtaining the required license (Butler 2012).

Conclusion: Toward Education

Addressing the challenges posed by the rapid advancement and proliferation of dual-use science and technology requires the development of a culture of responsibility among those engaged in the life sciences. Still, it is at best myopic and at worst dangerous to assume that biosecurity regulations and oversight mechanisms per se can be effective in this endeavor given the lack of established corresponding norms of research practice. The process of fostering biosecurity norms in biotechnology is multidimensional, but it requires, at the very least, that those on the front lines of research are sensitized and responsive to the ethical, social, and legal implications of their work. Indeed, a growing body of evidence suggests that when made aware of the potential risks and dangers associated with their research, life scientists are serious about their broader responsibilities and eager to contribute their expertise to strengthening the biological weapon nonproliferation regime (Whitby 2012). Biosecurity education is thus one possible way of overcoming the existing normative deficit in the life sciences and facilitating the dialogue between researchers, the security community, and policymakers. It is worth mentioning that the value of security education for those working in sensitive fields of science, such as nuclear science, has long been recognized and tremendous progress toward creating a culture of responsibility has been made.

According to the International Atomic Energy Agency (IAEA 2008), fostering nuclear security culture is essential for ensuring that “the implementation of nuclear security measures receives the attention warranted by their significance.” In order to help member states develop and implement relevant policies that maximize nuclear security, a comprehensive long-term capacity building strategy has been launched as part of the Nuclear Security Plans 2006–2009 and 2010–2013. The chief focus of the strategy is on nuclear security education and training. To this end, several important initiatives have been undertaken. For example, in 2010 the IAEA published a guiding document entitled Educational Program in Nuclear Security which aimed to facilitate the development of sustainable nuclear security human resource development programs (IAEA 2010a). The guide outlined a model of a Master of Science (M.Sc.) and a Certificate Program in Nuclear Security in order to provide member states with a comprehensive strategy for the implementation of nuclear security education and also to encourage universities and other educational institutions to develop relevant academic programs. Since then the number of universities offering accredited courses and degrees in Nuclear Security has been steadily increasing.

In March 2010, the IAEA actively supported the establishment of the International Nuclear Security Education Network (INSEN), as the Network was

considered an important and suitable mechanism to support and promote the sustainable implementation of nuclear security education. By design, the INSEN is a partnership between the IAEA and educational and research institutions and competent authorities. Its mission is to “enhance global nuclear security by developing, sharing and promoting excellence in nuclear security education” (IAEA 2010b). The Network’s activity covers a set of key areas, including but not limited to development of peer-reviewed textbooks, computer-based teaching tools, and instructional materials; faculty development through exchanges and training; joint research and sharing of scientific knowledge and infrastructure; and quality evaluation and assurance (IAEA 2010b). So far the INSEN comprises educational and research institutions from 26 countries on 4 continents, as well as 2 international organizations. Overall, the nuclear security education experience constitutes a valuable model for the development and implementation of biosecurity education for the life sciences, insofar as it is state led, all inclusive, and internationally coordinated based on a long-term strategic planning and clear targets.

In order to prevent the large-scale militarization of the life sciences, the responsibilities of researchers should be seen within the broader framework of the “web of preventive policies” centered on the BTWC. It is essential that practicing life scientists at all levels become fully aware of their responsibilities under the Convention, so that they can contribute their expertise to strengthening the biological weapons nonproliferation regime. To this end, the implementation of a comprehensive biosecurity *education* plan at international level based on the model of the nuclear security education experience could be viewed as a vital step in the process of fostering biosecurity *norms*. Only in this way will it be possible to ensure that attempts at the hostile misuse of life science knowledge and materials are effectively discouraged and prevented and that the life sciences continue to generate benefits for peaceful, prophylactic, and preventive purposes.

Neuroethics of Warfare

117

Gerald Walther

Contents

Abstract

International Humanitarian Law was established in the twentieth century to reduce the impact of warfare on civilians as well as to increase the protection of combatants. This chapter critiques its specific focus on the reduction of physical harm, while it does not take into consideration the impact of psychological harm onto civilians and combatants. Advances in neuroscience have shown that psychological well-being is linked with neuroanatomy and thus harm to the psyche is comparable to and even congruent with neurophysiological damage. The effects of stress and fear, which are abundant in modern warfare, are felt by combatants and noncombatants alike and have detrimental long-term effects. In addition, modern military doctrines, such as "Shock and Awe," used in the Iraqi invasion in 2003, specifically try to inflict fear and anxiety. While it may be argued that this leads to fewer casualties, the long-term effects of this doctrine may have unforeseen future consequences as societies suffer from

neurophysiological damage. Neuroethics is uniquely suited to critique current military doctrines and technologies and push for a revision of International Humanitarian Law to take into consideration and apply the insights about the human mind that neuroscience has uncovered.

Introduction

After the preceding chapters in this section have dealt with future interest in neuroscience research by the military, the legal implications of the use of these technologies, the education and awareness among scientists, and how norms can be developed in epistemic communicates such as neuroscience, this final chapter, instead of simply rounding off the section, takes the rather presumptuous title of "The Missing Neuroethics." What ethics is still missing? What has not yet been covered in this section?

The central topic of discussion within the chapter will be the relationship between fear, stress, pathologies, and military warfare. Starting point is a short summary of International Humanitarian Law, specifically *ius in bello*, and how it attempts to protect both combatants and civilians in warfare. Out of this overview, the argument is made that this protection is very limited and does not take into consideration the advances that neuroscience has made in understanding the relationship between psychological events, such as fear and stress, and its impact on human health, specifically neuropathologies. However, modern military doctrines such as "Shock and Awe," as used in the Iraqi invasion in 2003, as well as military interest in neuropharmacology, might increase the likelihood that both combatants and civilians become increasingly subjected to neuropathologies. Finally, the paper argues that neuroethics is uniquely suited to inform and change International Humanitarian Law to include psychological harm by showing its relationship with neuroanatomy. It can also inform neuroscientists how their research could be used by the military and the impact it can have on human security.

Contention: A Void in Humanitarian Law

As long as humans have engaged in warfare, there have always been calls for restraint on the methods of warfare. Within the Western world, the discourse on ethics and warfare was initiated by Christian theology. Early Christianity adopted a pacifist approach; however, as Johnson has argued, this ideology became more and more difficult to follow as time progressed and the Second Coming of Christ did not occur (Johnson 1987). As Christianity spread and soldiers within the Roman army converted, it became imperative to develop a Christian understanding of war that goes beyond pacifism and determines when a Christian is allowed to take up arms. In response to this need, St. Augustine of Hippo (354–430) developed the first theory of just war and started to differentiate between *ius ad bellum* and *ius in bello*,

i.e. just cause for war and justice in war's conduct, respectively. The issue was again taken up in the thirteenth century by St. Thomas Aquinas in his exploration of the justification of the Crusades. Eventually, Grotius (1583–1645) secularized the theory in his book on "The Laws of War and Peace," which is an analysis of international law as informed by natural law. As modern states started to emerge in the seventeenth century and wars were waged on national rather than local levels, the idea of an international law governing states received more attention. In the mid-nineteenth century, states started to develop formalized agreements on *ius in bello* issues, which are of primary relevance to this chapter, starting with regulations on how to treat wounded and sick soldiers in the field, which was later extended to armed forces at sea as well. The last addition after WWI pertained to the treatment of prisoners of war. After WWII all three agreements were reevaluated, and the protection of civilians in times of war was included. These agreements are the Geneva Conventions, which have since then been amended by additional three protocols: Protection of Victims of International Armed Conflicts, Protection of Victims of Non-International Armed Conflicts, and the Adoption of an Additional Distinctive Emblem. So what are some of these principles that are to be followed when engaging in warfare? How and to what degree does humanitarian law protect combatants and noncombatants?

In order to fight a war justly, the following principles need to be observed (Evans 2005):

1. Discrimination: One should not directly target those who do not directly participate in the war, and, in addition, one should take precaution to limit the casualties among these nonparticipants.
   (a) Doctrine of double effect: However, if an action that is justified by other criteria of the just war theory entails the deaths of nonparticipants, i.e., they are unintentional, then the war is not unjust.
2. Proportionality: The use of force deployed to achieve an objective has to be proportionate.
3. All noncombatants, which include prisoners of war, have to be treated justly.
4. All other international and national laws need to be followed as long as they are not fundamentally in conflict with the theory's moral requirements.

Of primary concern for this chapter is the first point of discrimination. It is more clearly defined in the Protocol Additional to the Geneva Convention relating to the Protection of Victims of International Armed Conflicts (Protocol I), 8 June 1977, specifically in Part IV, Civilian Population. Articles 48 through 51 outline who is considered a civilian and declare that civilians are granted special protection within war, e.g. that they cannot be objects of military actions, that indiscriminate attacks are prohibited, that they cannot be specifically targeted in war, and that any acts to spread fear among them are not allowed. In general, the goal of these provisions is to ensure that "[t]he civilian population and individual civilians shall enjoy general protection against dangers arising from military operations" (Art. 51.1). But what exactly comprises dangers? Evans' analysis of just war theory talks about avoidance of casualties with regard to the issue of discrimination in war (Evans 2005).

In his seminal work, "Just and Unjust Wars," Walzer uses historical examples to highlight certain issues within the just war theory and International Humanitarian Law (Walzer 1977). All of his examples related to civilian protection focus on physical harm, i.e. mostly people dying due to decisions of military commanders and the analysis discusses if these decisions were in accordance with humanitarian law. In his historical overview of humanitarian law, Solf claims that one of the four elements inherent in humanitarian law is that "loss of life and destruction of property must have some rational tendency to the prompt achievement of a definite military advantage" (Solf 1986). What is lacking in this evaluation of the "justness" of warfare is the psychological component and the damage that results from various types of military technologies and strategies. Of course, at the time of writing of these rules to protect civilians as well as combatants, our understanding of psychological pathologies had been limited. But this is where neuroethics will be able to make a fundamental contributions to the literature on human rights and international law by critiquing the emphasis on the purely physical dimensions of harm. As we progress in our understanding of the relationship between fear, anxiety, trauma, and pathologies, we may need to revise our definition of what harm is and what can be considered "acceptable" harm. And this analysis, although preeminent to the military warfare, stretches across other domains as well, for example, exercising control in prisons. In order to demonstrate where this type of analysis can lead us, this chapter will address the relationship between fear, anxiety, and trauma. Fear is particularly interesting because it is a tool that has been part of the military arsenal from traditional warrior societies to the modern military complex. And with our advances in understanding fear, the military will become increasingly capable to deploy it in even more sophisticated ways, e.g. using psychopharmacological agents. The next part of this chapter will look into our current understanding of the relationship between fear, anxiety, trauma, stress, and pathologies.

The Neuroscience of Fear and Its Psychophysiological Effects

What Is Fear?

While in our everyday life, the use of the word "fear" is quite frequent, and people appear to understand what is meant by it, which is to express some sort of experience of apprehension, in the scientific world, "fear" is rather ill defined and murky. As Rachman points out, it is very difficult to get people to talk about fears because of social stigma (Rachman 1978). For example, in warfare, soldiers are discouraged to think and admit their fears. And even absent a significant event like war, men are quite often culturally expected not to show signs of fear. Sometimes patients who suffer from fear are even unable to identify and recognize that they are afraid. These issues of admittance or recognition impair scientific study. But the study of fear also encounters a semantic barrier. People occasionally say that they are afraid of a certain event or object. However, once they are faced with this object,

they may not express any symptoms of fear at all. According to Rachman, it is also very difficult to quantify fear, because how does one translate expressions such as "terrified," "anxious," or "very frightened." As a result, a lot of work on fear has focused on the physiological and observable behavioral changes that occur when people say that they are afraid or in fear. Following Rachman, it is thus more useful to describe fear in terms of three components: "the subjective experience of apprehension, associated psychophysiological changes, and attempts to avoid or escape from fearful situations" (p. 3). However, as Rachman continues, these "three components often fail to correspond" (p. 3), which makes it "helpful to specify which component of a fear one is describing" (p. 3). Another distinction when talking about fear is between acute and chronic types. An acute fear might be, for example, triggered by seeing a snake, whereas chronic fears can either have a direct stimulus, e.g. the fear of being alone, or not. These latter are sometimes labeled anxieties that are more of an apprehension (Rachman 1978). Anxiety comes from within us (LeDoux 1999). Clinically speaking, fear and its accompanying physiological changes are adaptive in that they help us prepare for a specific danger, whereas anxiety is maladaptive and prevents us from functioning properly. Therefore, there are only anxiety disorders, but never fear disorder. According to the Diagnostic and Statistical Manual of Mental Disorder, Fourth Edition, Text Revision (DSM-IV-TR), the following anxiety disorders are classified: generalized anxiety disorder (GAD), social anxiety disorder (also known as social phobia), specific phobia, panic disorder with and without agoraphobia, obsessive-compulsive disorder (OCD), post-traumatic stress disorder (PTSD), anxiety secondary to medical condition, acute stress disorder (ASD), and substance-induced anxiety disorder (American Psychiatric Association 2000). According to Nutt et al., while these are specific disorders, each exhibits "shared features such as anxiety, certain physiological features and behavioural changes... These central features are also present in and indeed form the core of the other anxiety disorder-specific phobia," which is the equivalent of fear responses (Nutt et al. 2008, p. 365).

Given the varieties of fear and anxiety dimensions, it seems best to heed Rachman's advice to first describe what specific concept or version of fear one is investigating. This chapter will look at the psychophysiological dimension of fear and anxiety. However, instead of trying to understand what fear is, and thus differentiate between fears and anxieties, the focus is on elucidating how fears and anxieties manifest themselves and what their long-term effects are on the individual. In Rachman's description of the psychophysiological variables, i.e., "perspiring, trembling, or increased heart rate," that are employed to measure fear, it is noticeable that his book is slightly outdated – it was first published in 1978. Today, advances in cognitive neuroscience allow for a more detailed understanding of the psychophysiological changes associated with fear in terms of brain chemistry. It also allows for an inclusion of the concept of trauma and its relationship with fear, anxiety, and brain pathologies, which will be discussed in the last part of this section. The next part addresses the questions of what fear, anxiety, and trauma are in terms of neurophysiology.

The Neurophysiology of Fear and Anxiety

What fear and anxiety certainly share in common is the component of stress. When I find myself in a position of being afraid, it puts stress on my psychophysiological system. Given the larger context of this paper on the psychological effects of warfare, military technologies, and control, it is also necessary to look at the role of stress. So what is stress and what does it do?

Stress is brought on by aversive or dangerous situations, in which our system prepares our body to deal with the effects of a fight-or-flight scenario, which is either to fight the adversary or to run away. Normally, the accompanying changes to our system are only brief because running away and fighting are very short events. However, if there is no behavioral solution to a fight-or-flight event, we find ourselves in a state of prolonged stress response. This prolonged state can fundamentally affect our physiology and lead to pathologies that last for months or years. Carlson explained the neurophysiological effects of stress in his widely used textbook on "Physiology of Behavior," (Carlson 2013) and the following sections synthesize his discussion of this topic.

All emotions generally consist of a behavioral, autonomic, and endocrine response. Of particular interest to this chapter are the autonomic and endocrine responses. Of course, behavioral reactions to stress can also be dangerous, e.g., if a soldier under artillery fire runs out of the trenches because he wants to get away from the explosions. However, these are individual instances that are detrimental to the individual who displays such "inappropriate" behavior. But the autonomic and endocrine responses are shared by everyone in a stressful situation and are thus more important for this chapter. Both autonomic and endocrine responses are catabolic because they enable the body to mobilize all of its resources. The body activates the sympathetic branch of the autonomous nervous system, and the adrenal glands secrete epinephrine, norepinephrine, and steroid stress hormones. The results of the release of these hormones are manifold: epinephrine causes the nutrients in our muscles to be released in order to provide additional energy; it also, together with norepinephrine, increases the blood flow to the muscles and thus the overall blood pressure; cortisol, a steroid and glucocorticoid, helps to break down proteins and convert them into glucose, which allows fats to be made available for energy, increases blood flow, and affects the behavior by interacting with the brain. It also reduces the secretion of sex steroid hormones. As nearly all cells in the body contain glucocorticoid receptors, its effects are far from being understood completely. The release of glucocorticoids is mediated by neurons in the periventricular nucleus of the hypothalamus, which secrete a peptide called corticotropin-releasing hormone (CRH), which in turn stimulates the anterior pituitary gland, which in turn releases another hormone that eventually stimulates the adrenal gland. CRH is also secreted in the brain and has an effect on the limbic system, which is largely responsible for emotional responses and contains the periaqueductal gray matter, the locus coeruleus, and the central nucleus of the amygdala. Studies have shown that injection of CRH into the brain increases the acquisition of fear-conditioned responses and anxiety in rats.

But what about the health effects of stress, particularly long-term stress, on health? Carlson describes both the physiological and the neurophysiological effects. As already mentioned, glucocorticoid receptors are present in nearly all human cells. The effects of long-term release of the hormone are thus quite varied: increased blood pressure, damage to muscle tissue, steroid diabetes, infertility, inhibition of growth, inhibition of the inflammatory responses, and suppression of the immune systems. In addition to these primary effects, medical solutions to some of the issues cause secondary problems. For example, the long-term use of steroids to treat inflammations can result in cognitive deficiencies and lead to steroid psychosis, which includes several symptoms: profound distractibility, anxiety, insomnia, depression, hallucinations, and delusions. While all of these are very detrimental to the human being, it is even more important to understand what recent neuroscientific research has discovered about the neurophysiological effects of stress. Research has particularly focused on a few specific issues: glucocorticoid and neuron interaction, prenatal stress, early-life stress, and brief exposure to stress, all of which are coupled with high-stress and low-stress stimuli:

- General, long term: In animals, long-term exposure to glucocorticoids destroys neurons in the CA1 of the hippocampal formation. As this region is involved in memory and learning, stress might have permanent implications for these two cognitive abilities. Among elderly people, it has been shown that those with high blood levels of glucocorticoids learned a maze slower than those with normal levels.
- Prenatal, long term: In rats, prenatal stress interferes with hippocampal development as well, which impedes learning, memory, and spatial recognition tasks. In addition to its impact on the hippocampus, even mild prenatal stress produced permanent changes to the amygdala of unborn rats, which leads to a heightened sensitivity to fear.
- General, short term: Placing a rat in a plexiglass box into a cage with a cat for 75 min resulted in permanent changes in their neurophysiology. The glucocorticoid level increased five times, which caused changes in their spatial learning ability, and their primed-burst potentiation, which is a form of long-term potentiation, was reduced in their hippocampal slices. In addition, acute stress has also been shown to reduce the long-term survival of hippocampal neurons that are produced in the process of neurogenesis, which, when it is impaired in the hippocampus, has been linked with depression.
- Primates: While a lot of these studies have been conducted using rats, it has been shown that among vervet monkeys, who have a hierarchical social order, in which the ones at the bottom are continuously subjected to stress, some of these monkeys have died of stress. They suffered from gastric ulcers and increased adrenal glands, and in terms of their neuroanatomy, the neurons in their CA1 field of the hippocampal formation had been completely destroyed. Among humans who have been subjected to torture, brain degeneration has been documented with CT scans. In humans, even mild stress in early life reduced the volume of the dorsomedial prefrontal cortex. Similarly, chronic pain patients have reduced gray

matter in their cerebral cortex and particularly in the dorsolateral prefrontal cortex. In cognitive terms, chronic pain patients perform similarly poor on a task as those who have been affected by prefrontal lesions.

Post-traumatic stress disorder (PTSD) has also received widespread attention in the scientific community. According to the DSM-IV-TR, PTSD is caused when a person "experienced, witnessed, or was confronted with an event or events that involved actual or threatened death or serious injury, or a threat to the physical integrity of self or others" and "the person's response involved intense fear, helplessness, or horror". Its psychological symptoms include difficulty falling asleep or staying asleep, irritability, outbursts of anger, difficulty in concentrating, and heightened reactions to sudden noises and movements. In addition to these mental health implications, it also leads to poor physical health (Zayfert et al. 2002). In terms of the neurophysiological effects, they are very similar to those of a high-stress environment. Thus, specifically the hippocampus as well as the amygdala is affected. It has also been shown that the probability of suffering from PTSD positively correlates with the number of traumatic events that have been witnessed. This finding is supported by the evidence found in analyzing the hippocampal region of monozygotic twins, of whom one has fought in the Vietnam War. The war-exposed twins with PTSD had smaller hippocampal regions than those war-exposed twins without PTSD. Remarkably though, the PTSD soldier's twin who had not been in combat also had smaller than average hippocampal regions. Thus, the lower hippocampal volume is a result of the traumatic events, but people with a smaller initial hippocampal region are also more likely to develop PTSD. And if someone is exposed to traumatic events repeatedly, the hippocampal region decreases with each event and eventually reaches the threshold when symptoms start to appear.

The initial focus of this section was on fear and anxiety, which was then turned into a discussion about the effects of stress. Of course, stress in the animal research that has been discussed has been induced in the animals by creating a situation where the animal has been put in a fearful situation, e.g. exposing a rat to a cat. While the result of the physiological effects of producing a fight-or-flight scenario has been helpful for our survival, this last section has shown that even these short bursts have a negative impact on our neurophysiology. However, the most problematic changes only occur in prolonged states of stress or high-stress traumatic events. Going back to the earlier distinction between anxiety and fear, the former being considered maladaptive and the latter useful, it is scientifically warranted to lose this distinction (Blanchard and Blanchard 2008). Blanchard and Blanchard argue that there is no biological basis to support this normative judgment. Both animal and human defense reactions (Blanchard et al. 2001) to an adverse scenario are tightly controlled by the specific features of the danger and very consistent and robust (Blanchard and Blanchard 2008). Thus, anxiety and fear behavior may just be the two strategies that have enabled us to best survive in dangerous situations. For example, in rats, the direct exposure to a cat elicits a fear response, whereas putting cat hair or odor next to the rat results in the display of an anxious behavior (Adamec et al. 1998). Both may be useful in the

short run, i.e. to survive, but detrimental in the long run, i.e. the effects of stress on the physiology and neurophysiology as discussed previously.

The Hidden Harm of Warfare and Violence

In the 2003 invasion of Iraq, the US military used a strategy called "Shock and Awe," which was developed for the National Defense University by the Defense Group Inc. already in 1996 (Ullman and Wayde Jr 1996). The goal of "Shock and Awe" is not to use overwhelming force to defeat the enemy, the primary doctrine of the USA at that time, but rather to undermine the willingness of the enemy soldiers to continue or even start to fight. In the Iraqi invasion, this was achieved by hitting Baghdad with several hundred cruise missiles to specifically target command headquarters instead of actual weapons systems. As one pentagon official remarked prior to the invasion, "there will be not be a safe place in Baghdad" (CBS News 2009). Of course, from the point of view of the invading army, in this case the USA, it is certainly advantageous to reduce the morale of enemy soldiers and maybe not have them fight at all. It may even be argued that it leads to fewer casualties. However, as we have seen from the evidence on how stress results in neurophysiological damage, it is not the case that there is no harm done using this method. In fact, this warfare does not differentiate between soldiers and civilians at all. "Shock and Awe" targets and affects everyone. Of course, the effect will be different on the specific populations, e.g., soldiers, civilians, and children. As we have seen in the studies on prenatal and early-life stress on rats, children are especially vulnerable as the impact of stress directly impedes their natural neurodevelopment and cause lifelong mental deficiencies. Research has shown that negative events in early life increase the chance of psychopathologies such as post-traumatic stress disorder (Paolucci et al. 2001), social anxiety (Binelli et al. 2012), or general anxiety disorder (Phillips et al. 2005). The effect on soldiers might also be heightened compared to a normal civilian for a variety of reasons. Warfare is highly ritualized. Van der Dennen's discussion and analysis of warfare among traditional societies show the various types of rituals that are conducted before as well as after the actual combat (Van der Dennen). Most of the pre-warfare rituals serve to protect the warriors against harm, e.g. praying for the warriors, giving the warriors charms and amulets, divination, asceticism, sacrifice, vows of the warriors to be victorious before the community, decorations like body painting, or rehearsal of the battle, which are enacted in advance and show that they will be victorious. However, these rituals do not only try to persuade and convince the warrior that he will not be harmed. They serve as a reminder of the duty to protect their society, as a means to enhance the belief in one's own strength and to protect against fear and instill fear in the opponent. While soldiers hardly face each other directly in modern warfare anymore, instilling fear in the enemy is achieved via superior military technology or strategy, e.g., the "Shock and Awe" doctrine. In addition, what distinguishes the modern soldier from a traditional warrior is that the warrior retains the right to enter into negotiation and talk to the enemy. To a modern soldier, this possibility does not

exist. Thus, the only solution to escape the fear and stress of combat is to flee, which is desertion for the individual soldier. Of course, since the soldier has undergone the blessings of his community, this action carries a high social stigma. He did not only abandon his fellow soldiers but also the community for whom he was fighting. Thus, in addition to potential neurological damage due to stress, the soldier also faces additional stress due to his failure as a soldiers in the eyes of his comrades and the community, which could result in further damage.

A military doctrine like "Shock and Awe" is only one aspect of modern warfare and violence that societies face. Post-traumatic stress disorder does not only happen to the soldiers of the losing military. The victorious military and its society also face the burden of having to deal with these traumatized, and as we have seen, actually brain-damaged soldiers. Also, terrorism is in its psychological effects similar to the "Shock and Awe" theory in that it tries to show those societies that the terrorists are "in war" with that no one in the society is safe from their attacks. Thus, if a suicide bomber blows himself up, there are three categories of victims: those directly harmed or killed in the attack, the bystanders who witnessed the attack, and the general society who have to be afraid that they could be a potential victim next time. Members in the two last groups could equally suffer from neurological damage and accompanying behavioral changes. While military warfare and terrorism are more prone to cause the types of stress and damage that have been discussed, the issue does not only pertain to those two. For example, victims of torture show brain degeneration in CT scans (Carlson 2013). Similarly, solitary confinement of prisoners may also cause behavioral and neurophysiological changes. For example, in rabbits it has been shown that rabbits raised individually in a cage show higher fear levels and incomplete behavioral patterns than their peers who were raised in a group (Trocino et al. 2012).

Conclusion

International Humanitarian Law has been developed in the last century to protect civilians and soldiers in warfare. However, its focus on physical safety may need to be enlarged to account for the neurophysiological damage that can be caused by stress, which is a product of fear and anxiety. These neurophysiological changes can be permanent and may be highly detrimental for society to return to or transition into a peaceful society. Modern military doctrines like "Shock and Awe," which was applied in the 2003 Iraqi invasion, specifically try to create fear in the enemy soldiers, which nevertheless also target the civilian population to an equal degree. As neuroscience advances, it is likely that military technology will be better able to produce fear in the enemy, for example, via neuropharmacological agents. For example, while fear inducement is not specifically mentioned in a 2008 report by the "Committee on Military and Intelligence Methodology for Emergent Neurophysiological and Cognitive/Neural Science Research in the Next Two Decades," the use of technologies for degradation, i.e. the decrease of the abilities and skills of the enemy, is considered a field of potential benefit for the military and the intelligence community (National Research Council 2008). Neuroethics is

uniquely positioned to inform the international community of the danger of fear inducement and to show the hidden costs of war and violence. It can also raise awareness among neuroscientists of the need to be informed about the possibility of misuse of their research and how it can impact on military warfare.
